[4] We gratefully acknowledge the assistance and patience of Mr. Fred Hardwick and other employees of Huntington Alloys, Inc., Huntington, W. Va., and the technical and editorial assistance provided by Dr. J. Stuart Warner of INCO Limited, Toronto, Canada. Ms. Michele LaValley, Mrs. Vanessa Gleason, and Mr. Donald Fisherowski assisted in the data processing operations, and Miss Mary Preininger provided the computer programming support. We are also deeply appreciative of the late Mr. Kenneth Wassam for his dedication and enthusiasm while serving as project director in the early phases of this study.

operation. This group included active employees, service and disability pensioners, and employees who were laid off as of January 1, 1948, but who were recalled sometime during the year 1948. The completeness of the company files for active employees was verified by a comparison of names obtained from personnel records of men who worked a year or more with names that appeared on the quarterly social security tax return the company had filed with the U.S. Internal Revenue Service for the first quarter of 1948 and the first quarter of 1949. No names were missing in the personnel records. This verification process was fully described elsewhere (*4*).

This group of 1,855 men was further subdivided with respect to exposure to the calcining operations. Personnel records indicated that 109 of these men had worked in the calcining department for a year or more. In addition, 157 men had worked a year or more in the melting and casting department. Since this department was physically adjacent to and shared seniority with the calcining department, many of these men probably were exposed at some time to the calcining operations, although their personnel records do not explicitly show this. For the purpose of this investigation all 266 refinery workers were considered as having been exposed to calcining operations, and the combined operations will be referred to simply as "refinery."

Of the remaining 1,589 men hired before 1947, some 137 had worked in either the calcining or melting and casting departments but for less than 1 year. Thus 1,452 or 91.4% of these men had never worked in the refinery and were not exposed to the calcining operations. This group of 1,589 men will be referred to as "nonrefinery workers."

The total of 1,855 workers were followed for deaths from January 1, 1948, through December 31, 1977, with results as shown in table 1. The vital status of 1,657 or 89.3% of the study members was known from plant records, either because they were still employed, had died while employed, or had retired under pension plans in which they were, in effect, followed by the company. The vital status of all but 10 of the remaining study population was determined through various follow-up resources including the Social Security Administration, the U.S. Postal Service, the Veterans Administration, and direct telephone inquiries. Overall, 99.4% of these workers were traced and of the 791 who were known to have died, death certificates were obtained for 789 or 99.7%. All death certificates were coded by an independent nosologist to the Seventh Revision of the ICD.

An additional group of 1,354 male employees who worked for a year or more during 1948–59 but who could not have been exposed to the calcining operations was identified in the company's personnel records. All but 9 of these men were hired after 1947, i.e., after the calciners had been removed. Nine of them had been hired in 1947, but their positions were such that they would have had no opportunity for exposure to the calcining operations. While this group had no exposure to the calcining operations, it did share some of the exposures of the refinery group inasmuch as some of these men worked for a year or more in the melting and casting department. This group will be referred to as "hired after 1946."

TABLE 1.—*Follow-up results for male nickel workers who were on the company payrolls January 1, 1948, and who had worked a year or more*

Vital status as of 12/31/77	No.	Percent[a]
Alive	1,054	56.8
Dead	791	42.6
Death certificate found	789	(99.7)
No death certificate found	2	(0.3)
Lost to follow-up	10	0.6
Total	1,855	100.0

[a] *Numbers in parentheses* are not part of the overall total of 1,855 but are subgroups of the 791 deaths.

The completeness of this group has not been verified, but the fact that no names were missing from files for men hired earlier suggests that this cohort was probably fully identified. These men were also followed for deaths through 1977 with results as shown in table 2. The vital status of 777 or 57.4% of the group hired after 1946 was known from plant records, whereas the vital status for all but 9 of the remaining study members was determined through the same tracing resources used with the first cohort. As in the first cohort, over 99% were traced. For the 94 study members who died, 97.9% of the death certificates have been located. All death certificates were coded by an independent nosologist to the Seventh Revision of the ICD. For both cohorts, observed numbers of deaths were compared to numbers expected based on the mortality experience of the U.S. white male population. For the computation of the expected numbers, person-years of observation were allocated to 5-year age and calendar time categories and multiplied by corresponding cause-specific U.S. death rates (*5*). To adjust for geographic variations in mortality, we also computed expected numbers of deaths based on the white male population of the 6-county area surrounding the Huntington plant from which the work force was largely drawn (Cabell, Wayne, Mason, Putnam, and Lincoln Counties, W. Va., and Lawrence County, Ohio). The local mortality rates are available for cancer for the years 1950–77, but for other causes of death rates are available only for the years 1962–77. Where appropriate, U.S. and local death rates were adjusted to the Seventh Revision of the ICD through the application of comparability ratios published by the U.S. Public Health Service (*6*). Ratios of observed-to-expected numbers of deaths were expressed as SMR, which are estimates in percentage form of rate ratios for nickel workers compared to those for the standard population, adjusted for age and calendar time to the person-years distribution of the employment group of interest. If one assumes that the observed

[a] Expected deaths are based on total U.S. white male mortality rates.
[b] Number at risk: 266. Person-years at risk: 6,738.9.
[c] Number at risk: 1,589. Person-years at risk: 39,380.9.
[d] Number at risk: 1,354. Person-years at risk: 31,203.8.
[e] $P<0.01$.
[f] $P<0.05$.

number of deaths follows a Poisson distribution, confidence intervals can be placed on the SMR and significant deviations of the SMR from 100, indicating deficit and excess mortality risks, can be identified (*7*).

RESULTS

Table 3 shows the mortality experience of the following 3 groups of workers compared to that expected based on the total U.S. white male mortality experience: 1) those hired before 1947 who worked a year or more in the refinery, 2) those hired before 1947 who worked a year or more but not a year or more in the refinery (nonrefinery), and 3) those who were hired after 1946—too recently to have worked a year or more in the refinery. Among refinery workers (as defined) SMR were elevated for nearly every cause shown. A notable exception is the category "all heart disease" where a 13.8% deficit in deaths was observed. The excess in respiratory cancer is mainly due to the two deaths in the "other [respiratory cancer] (residual)" category. Both of these deaths were from sinonasal cancers, and the excess is statistically significant. One of these men worked at the calciner from 1941 to 1944. The personnel records of the other show that he worked in the melting and casting department.[5] As indicated above, however, since seniority was in the combined departments, the second man possibly spent some time at the calciner. The excess in nonmalignant respiratory disease among refinery workers is of interest due to the high dust levels in matte crushing, grinding, and handling. This excess is mainly due to influenza and pneumonia, however, and may not be due to work in the refinery. Curiously, there is no large excess in lung cancer among these refinery workers.

Among workers who were employed before 1947 and who did not work a year or more in the refinery, table 3 shows that there was a statistically significant deficit for "all causes." For individual causes SMR were somewhat lower than those for refinery workers and were generally not in excess. For nonmalignant respiratory disease there was a significant deficit in mortality. Under coding rules in effect for the Seventh Revision of the ICD, there were no deaths codable to sinonasal cancer. However, 2 deaths were noted with a known clinical diagnosis of sinus cancer. For one of these the death certificate diagnosis was listed as "carcinoma of ethmoid." Under the Seventh Revision of the ICD this death was to be coded to bone cancer. It is of interest, however, that under the Eighth Revision of the ICD this death would have been coded to sinonasal cancer. For the other death, the death certificate diagnosis was "cancer of the left maxillary." Under both the Seventh and Eighth Revisions of the ICD, this death would be coded to bone cancer. Biopsies on these two cases showed that they were probably carcinomas. The pathologist believed that they both fit a category known as "Schminke tumors"—a nasopharyngeal cancer. Richard Doll (personal communication to J. S. Warner, Oct. 8, 1980) reviewed these two cases and believed that they were compatible with a diagnosis of poorly differentiated squamous cancer of the nasal sinuses. One of the sinonasal (nasopharyngeal?) cancers among men who were employed before 1947 and who did not work a year or more in the refinery was in a man who worked in an acid-reclaim plant where copper-nickel carbonates were precipitated from pickling solutions and decomposed to copper-nickel oxide at about 1,000°C. The other was in a millwright in the polishing mill adjacent to the acid-reclaim process. It is believed that this worker did maintenance work in the acid-reclaim plant.

---

[5] During 1914–19 this man worked as a heel finisher in a shoe factory. Shoe factory workers appear to have an increased incidence of nasal cancer (*8*).

Among workers hired after 1946 table 3 shows that the SMR were generally low. There have been no deaths from sinonasal cancer among these workers. There was a slight excess in digestive and lung cancer deaths, however, and in deaths from stroke. The pattern of mortality among these workers is similar to that among refinery workers.

Table 4 summarizes some of the information available on the sinonasal cancers. Included here are estimates of nickel exposure. These will be discussed below.

In the calculation of the SMR for table 3, the expected number of deaths was derived from the experience of the entire white male population of the United States. The population in the Huntington, W. Va., area has a mortality experience differing somewhat from that of the entire United States, and some of the excesses and deficits in SMR shown in table 3 are due to this difference.

Table 5 shows how SMR differ if based on U.S. death rates, State of West Virginia death rates, and death rates for the counties in the Huntington area. Generally, local rates are higher than U.S. death rates so that the workers' mortality appears more favorable when a local comparison group is used. SMR for respiratory cancer and for stroke are lower, and the excess shown in table 3 among workers hired after 1946 disappears. However, a slight excess emerges in the cause-of-death category "leukemias-lymphomas." Use of local rates for comparison is probably the more valid, and these rates will be used where cancer SMR are calculated in the tables that follow.

Table 6 is similar to table 3 except that in table 6 only cancer mortality is shown and only those cohort members who lived 20 years or more after first exposure are examined. Also, local death rates are used in the calculation of expected deaths rather than U.S. rates. The period 20 years since first exposure is of particular interest since if carcinogens were in the environment of the plant, they probably would not produce a detectable cancer excess until this period had expired.

Table 6 shows a 40.5% excess in overall cancer mortality among the refinery workers. Only the excess for the category "other respiratory cancer" is statistically significant, however, which is due to the two sinonasal cancers discussed previously. Lung cancer does not show an important excess. For nonrefinery workers hired before 1947, SMR are only slightly elevated, but there is no important excess in respiratory cancer. Workers hired after 1946 have a low overall death rate for "all cancer" and for most sites. For all 3 groups mortality from leukemia-lymphoma is elevated, although in two instances numbers of deaths are very small. Generally, the picture we see here is a cancer death rate receding from somewhat elevated rates apparently associated with work in the old refinery.

Table 7 shows for both cohorts combined the relationship between respiratory cancer deaths and interval from onset of employment and duration of employment. The interval from onset of employment and possibly the duration of employment show some direct relationship to respiratory

TABLE 4.—*Deaths probably due to sinonasal cancer*

Date of hire	Dates at refinery	Work history	Date of death	Death certificate diagnosis	Cumulative nickel exposure,[a] mg Ni/m^3 mo		Average nickel exposure,[a] first 20 yr, mg Ni/m^3

cancer mortality. None of the SMR are statistically significant, however. These findings were consistent for both the refinery and nonrefinery workers when analyzed separately.

Table 8 shows estimates of nickel exposure made by the company for each department. These estimates are intended to represent average airborne concentrations of nickel in all forms over an 8-hour shift. Estimates have been derived by the use of limited historical sample data obtained by the midget impinger-particle counting technique and converted to modern gravimetric expression. In addition, data derived from several hundred recent gravimetric samples were used to estimate historic exposures. Whenever possible and/or applicable, the modern data were adjusted on the basis of a knowledge of process changes and environmental controls that were implemented over the years. The unadjusted extrapolation of modern sample data to historical exposures is imperfect, but it can be assumed that the historical exposures were the same or, in most cases, of greater magnitude. Substances to which workers were exposed in addition to nickel were those commonly contained in the alloys and processing. Some of these materials were chromium, iron, copper, grinding dust, solvents, and acid mists. The historical data indicate very high levels of dust at the calciner, but it was not possible to determine the various components of the dust or to identify all the species of nickel. However, the calciner is the only area where a significant exposure to nickel subsulfide, a potent nickel carcinogen in animals, would be likely.

Using the departmental exposure estimates shown in table 8, one can calculate for each worker an estimate of his cumulative and average nickel exposure based on departmental assignments, as shown in personnel records, and relate this exposure to his mortality experience. Table 9 shows SMR for respiratory cancer by a time-weighted cumulative measure of nickel exposure for each of the 3 groups of workers shown in tables 3 and 6. As in table 6, expected respiratory cancer deaths are based on the local mortality experience.

Table 9 shows some trends in respiratory cancer mortality related to exposure. However, these trends are not consistent. Refinery workers at the highest exposure level have the greatest respiratory cancer excess, but for nonrefinery workers at this exposure level there is a deficit. The four cancer cases described in table 4 did not have unusually high nickel exposures. Three would fall in the exposure group 50–99 mg Ni/m^3 months, whereas one would fall in the highest grouping 200 or more. Only the two sinonasal cancers among refinery workers are included in table 9, and the presence of these cancers does not greatly affect the trends shown.

One problem with table 9 is that for those who died exposures are counted up to the time of death. Exposures during some period before a death from respiratory cancer would probably have little to do with the respiratory cancer and should, therefore, be excluded. In addition, respiratory cancer deaths could have been included that occurred within 20 years of hire, and as noted in table 6, these deaths probably would be unrelated to exposure at the plant due to long latent period for this type of cancer. These two problems are partly corrected in table 10 where only exposure during the first 20 years from date of hire is related to mortality 20 years or more after date of hire. The dose-response relationship is somewhat weaker here in contrast to that seen in table 9. Removal of the two sinonasal cancers has little effect on the relationships shown in tables 9 and 10 so that there is apparently a slight direct relationship between nickel exposure and lung cancer. This relationship is probably not simply the result of confounding due to combining unlike subgroups because there is some evidence for a direct relationship in the 3 subgroups.

If exposure groups in table 10 (r=0.53) are recombined as shown in table 11, a much stronger relationship emerges (r=0.79). We do not know whether this is an artifact because these exposure categories were deliberately chosen from those in table 10 to produce a stronger relationship. The relationship shown here and in tables 9 and 10 holds when rates are adjusted by the direct method, so it is not an artifact resulting from use of an indirect adjustment method. Even in the highest exposure category, however, the SMR is not greatly elevated, and none of the SMR are statistically significant. The linear regression equations derived from data in tables 10 and 11 are very similar. For table 10 the regression equation is $y=101.66+0.11x$, whereas for table 11 it is $y=96.27+0.12x$. Thus, if this represents an underlying relationship, it is not much affected by regrouping as in table 11. This model predicts very little response at zero dose. A better fitting model ($r=0.99$) for the data in table 11 is a logarithmic model of the form $y=a+b \ln x$; however, this model is not appropriate for predicting response at zero dose.

One question that might be raised about table 11 is whether the nonrefinery group may show a dose-response relationship because of some brief exposure in the refinery. Of the total 1,589 men in the nonrefinery group, 138 actually worked briefly in the refinery (<1 yr). However, the respiratory cancer death rate in this group of 138 men was not excessive (SMR=74.9). Thus the inclusion of this small group of men with the nonrefinery group is not the reason for the dose-response relationship shown in table 11.

Probably a more important question is whether the dose-response relationship shown in table 11 is peculiar to respiratory cancer or applies to several or all causes of death. If several causes of death are involved, particularly deaths other than cancer deaths, then evidence that nickel is related

to respiratory cancer in this instance would be weakened. Table 12 shows for both cohorts of nickel workers SMR by dose for several causes of death. There is a weak dose-response relationship for all causes of death, which, however, is primarily due to a direct relationship between dose and cancer deaths. Other major causes of death categories do not show any marked relationship to dose. Within the cancer category the relationship is with digestive, respiratory, and genitourinary cancers. Further subdivision of the categories "digestive and genitourinary" shows that there are slight excesses in stomach and prostate cancers and that these cancers are related to dose. Colorectal cancer was not in excess but was also dose related. The high SMR (441.2) for other digestive cancers in the highest dose category was due to two cancers in the cause-of-death category "cancer of the liver and biliary passages." One was a cancer of the gallbladder, and one was a malignant hepatoma. Both men with these cancers had worked at the calciner. Overall, however, this cause-of-death category was not in excess (observed, 4; expected, 4.2). A Russian study has implicated nickel in stomach cancer, and a recent study of nickel platers suggests a stomach cancer excess (*9, 10*). A statistically significant prostate cancer excess has been reported for workers at mines, mills, and a smelter in the Sudbury area of Ontario (*11*). We do not know of any other studies reporting colorectal or liver cancer in nickel workers, and perhaps our observations on these cancers are unimportant.

DISCUSSION

The discovery of sinonasal cancer among nickel refinery workers at Huntington, W. Va., is important, particularly in light of similar findings in other studies. While only one sinonasal cancer was clearly related to actual nickel refining (calcining), given the small number (109) of workers in that operation the relative risk there was very high. Other studies have suggested that furnace work in nickel refineries carries a high risk of producing sinonasal cancer [(*1–3*); Sutherland RB: Mortality among sinter plant workers. Toronto: Report of the Division of Industrial Hygiene, Ontario Department of Health, 1969]. There is evidence here that sinonasal cancer patients had worked in acid reclaim, a high-temperature decomposition process, and these findings may support that theory. The actual nickel exposure of the sinonasal cancer patients was not unusually high.

For lung cancer there was no marked overall excess, which is an unexpected finding in view of an excess reported in other studies. It would seem that if exposure to nickel or its compounds produced sinonasal cancer at the Huntington refinery, a greater excess in lung cancer should have appeared. Nickel exposures may have been considerably lower at Huntington than in other studies, however. It has been noted that dust concentrations around the calciners were much lower than those at Clydach, Port Colborne, or Copper Cliff (International Nickel Co., Ltd.: Nickel and its inorganic compounds. Report submitted to the National Institute for Occupational Safety and Health, Oct. 1976), which may in part account for the lack of any large excess. It is also possible that lower or different exposures are involved in sinonasal cancer than in lung cancer. However, the fact that there is some evidence of a dose-response relationship for lung cancer suggests that even at these lower exposure levels, some causal relation between lung cancer and nickel exposure may have been present. The problem may be simply one of detecting an excess at these lower exposure levels. Stomach and prostate cancers have been reported in excess in other studies, and it may be significant that in this study these cancers are slightly in excess and appear to be dose related.

Cell-Mediated Immunity to Mouse Mammary Tumor Virus Antigens by Patients With Hyperplastic Benign Breast Disease[1,2,3]

G. B. Cannon,[4] S. H. Barsky,[5] T. C. Alford,[6] L. F. Jerome,[4] V. Tinley,[6] J. L. McCoy,[7,8] *and* J. H. Dean[4,9]

ABSTRACT—Peripheral blood leukocytes of patients with preoperative breast cancer, benign breast disease, and benign gynecologic disorders and normal healthy females were tested, as blind coded specimens, with murine mammary tumor virus (MuMTV) antigens in the direct and indirect leukocyte migration inhibition (LMI) assays. The incidence of reactivity by patients with breast cancer was low. (From 5 to 35% breast cancer patients reacted, depending on which group of control individuals they were compared to and what antigen was used.) Nonparametric analyses showed no differences between control groups (normal donors and patients with gynecologic disorders) and breast cancer patients with either assay. However, there was a significant difference between benign breast disease patients with hyperplasia and 1) benign breast disease patients without hyperplasia ($P<0.03$) and 2) patients with gynecologic disorders ($P<0.04$) in the direct assay when it was performed blindly with the gp52 antigen. Patients with hyperplasia (benign breast disease as well as breast cancer) had a higher incidence of enhanced migration in the indirect test than breast disease patients without hyperplasia. The enhanced migration to the MuMTV was correlated to enhanced migration to a 3-*M* KCl extract of the breast cancer cell line MCF-7 in simultaneous tests. Thus the LMI assays with MuMTV antigens do not appear valuable in breast cancer diagnosis, but they may help to identify a small group of benign breast disease patients whose breast pathology is thought to be associated with a high risk for developing breast cancer.—JNCI 1982; 68:935–943.

The MuMTV has been shown to have some immunologic relationship to human breast cancer. Antibodies to the glycoprotein coat (gp52) of the MuMTV were found to bind to breast tumor tissue and not to normal tissue (*1*), and IgG in the sera of breast cancer patients bound to MuMTV-infected cells (*2, 3*). IgG binding to MuMTV was seen more frequently with sera from breast cancer patients than with sera from patients with benign breast disease or from normal individuals (*4*). Leukocytes from postoperative breast cancer patients were also found to react to MuMTV in the LMI assay (*5, 6*).

Although the basis for the development of breast cancer-associated reactivity against MuMTV antigens is unclear, it seemed possible that detection of such activity might be useful for early diagnosis of cancer or for detection of groups of women at high risk of developing breast cancer. The present study was set up to evaluate the possible application of the LMI assay with MuMTV antigens in the diagnosis of breast cancer. Preoperative patients with breast disease as well as normal hospital workers and preoperative patients with a variety of benign gynecologic diseases were tested in the direct and indirect LMI assays. Since a considerable portion of patients with benign breast disease were found to be reactive, their lesions were classified according to the degree of hyperplasia, and this information was compared with the LMI results to determine whether LMI reactivity was associated with a particular type of benign breast disease.

MATERIALS AND METHODS

Source of leukocytes.—Leukocytes were obtained from heparinized whole-blood samples that were sent under code from the George Washington University Hospital, Washington, D.C. All blood donors were from this hospital and included patients just prior to biopsy for evaluation of breast disease (and subsequently shown to have either breast cancer or benign breast disease), patients with benign gynecologic disorders, and normal female hospital personnel. The mean ages in years and age ranges for each of these groups were as follows: breast cancer patients, 56.5 (24–85); patients with benign breast disease, 41 (19–76); patients with gynecologic disorders, 41 (26–57); and normal female hospital personnel, 33 (21–64).

Pathology.—All breast biopsy specimens had been previously processed for routine light microscopy. This procedure included extensive sectioning of each biopsy specimen, fixation in 10% buffered Formalin, dehydration in a series of graded alcohols (70–100%) and xylol, paraffin embedding, 6-μm cryostat sectioning, and staining with hematoxylin and eosin.

Histologic sections of all the biopsy specimens of the

Abbreviations used: HAN=hyperplastic alveolar nodules; LMI=leukocyte migration inhibition; MI=migration index (indices); MuMTV=murine mammary tumor virus; PAGE=polyacrylamide gel electrophoresis; PBS=phosphate-buffered saline; PMN=polymorphonuclear; PPD=purified protein derivative.

benign breast lesions were reevaluated without knowledge of the LMI results. The sections were classified into categories 0 through 5 according to the magnitude of proliferation of epithelial cells. The categories were: 0) fat or stroma, occasional cysts; 1) prominent cysts, apocrine metaplasia, focal adenosis; 2) prominent sclerosing adenosis, crowding of ducts and acini, prominent apocrine metaplasia, but no intraductal proliferation; 3) intraductal proliferation either in the form of papillomatosis or hyperplasia; 4) intraductal papilloma; and 5) extremely atypical hyperplasia. A number of the cases had more than one biopsy more than 1 month apart; these were consistently placed in the same category, and the reader was unaware that there was a previous biopsy and what the classification of the biopsy specimen was.

Antigens.—MuMTV, purified from the supernatant of the mouse mammary tumor tissue-cultured cell line MM5 by density gradient sedimentation, was obtained from the NCI-Frederick Cancer Research Facility, Frederick, Md. The gp52 was supplied by Dr. Wade Parks, University of Miami School of Medicine, Miami, Fla., by a method previously described (*7*).

The MCF-7 antigen was a 3-*M* KCl extract prepared from a large pool of this human breast cancer-derived cell line by a method described previously (*8*).

Direct LMI assay.—The direct LMI assay measures the capacity of the test individual's lymphocytes to produce a lymphokine in response to the antigens and also the capacity of their PMN cells to respond to the lymphokine by inhibition of migration. The procedure has been described previously (*8*). Leukocytes were separated from red blood cells by gravity sedimentation of heparinized whole blood on Plasmagel and incubated with the antigen (25 µg MuMTV, 50 µg MCF-7, or 0.5–1 µg gp52) at 37°C for 45 minutes. They were then drawn into 25-µl capillary pipettes, which were then centrifuged, cut, and placed in Sterilin chambers to which McCoy's 5-A medium, supplemented with 10% fetal bovine serum and 100 µg gentamicin/ml, had been added. After the mixture was incubated for 18–24 hours, the circles of migration (×20) were projected onto paper with an inverted microscope, drawn, and later measured by planimetry. The data were expressed as an MI, which is the mean migration area of four replicates in the presence of antigen divided by the mean migration area of four replicates in the absence of antigen.

Indirect LMI assay.—The indirect LMI assay measures the capacity of the test individual's lymphocytes to produce a lymphokine in response to the antigen. Lymphokine production is then measured by a test of the culture supernatant for inhibition or enhancement of migration of a normal donor's PMN cells. The procedure was described previously by McCoy et al. (*9*). Mononuclear cells were separated from whole blood by Ficoll-Hypaque (lymphocyte-separating medium; Litton Bionetics, Inc., Kensington, Md.) flotation. Cells were washed with PBS, concentrated by centrifugation, and adjusted to a concentration of 1×10^6 cells in RPMI-1640 medium with 1% human serum (blood group AB), glutamine, gentamicin, and HEPES[10] buffer, and 0.1 ml was dispensed into microtubes (Bel-Art Products, Pequannock, N.J.). Antigen (25 µg MuMTV or 50 g MCF-7) was added in a 0.1-ml volume. Control tubes contained 0.1 ml medium without antigen in addition to the cells. Tubes were incubated for 2–6 hours and centrifuged for 5–10 minutes at 200×*g*, and the supernatants were removed. Fresh medium (0.2 ml) was added to each tube, and the cells were resuspended and incubated at 37°C for 24 hours. The supernatant containing the lymphokine was removed, stored at −70°C for 1–2 weeks, and then assayed on the donors' PMN cells. The PMN cells were obtained from heparinized blood by a two-step procedure. Whole blood was layered onto Plasmagel and incubated for 45–60 minutes at 37°C. The fluid layer was removed, diluted with PBS up to 40 ml, and underlaid with 10 ml Ficoll–Hypaque. After centrifugation at 400×*g* for 30 minutes, the PMN cells were located in the pellet. After resuspension and washing once, the PMN cells were resuspended in agarose at 1×10^6/ml and dispensed by droplets into flat-bottom wells of microtiter plates. When the agarose solidified after 1–2 minutes, 0.1 ml of tenfold dilutions of the supernatant to be tested diluted was added to each well. After the mixture containing PMN cells and supernatant was incubated, at 37°C for 18–24 hours in a 5% CO_2 incubator, inner and outer circles were traced from projections of a microscope with a 10× lens. The net area of migration was then calculated. The MI was the mean of the replicates for the experimental group divided by the mean of the replicates for the control culture supernatant.

Statistical analysis.—MI of the various clinical groups were compared by the Wilcoxon rank sum test, or the proportions of reactive individuals in the various groups were compared by chi-square analysis.

To define reactive individuals, we used cutoffs based on the MI of 3 groups of control individuals. The cutoff was set at the lower tenth percentile of the results of the control group so that 10% or less of the MI values of the control group would fall below it. The 3 groups of controls were: 1) the normal donors, 2) the patients with preoperative gynecologic diseases, and 3) the preoperative patients in the combined benign breast disease categories 0, 1, and 2 (i.e., the group lacking intraductal proliferation). Thus it was possible to determine the reactivity of cancer or benign breast disease patients relative to that of the 3 groups of controls.

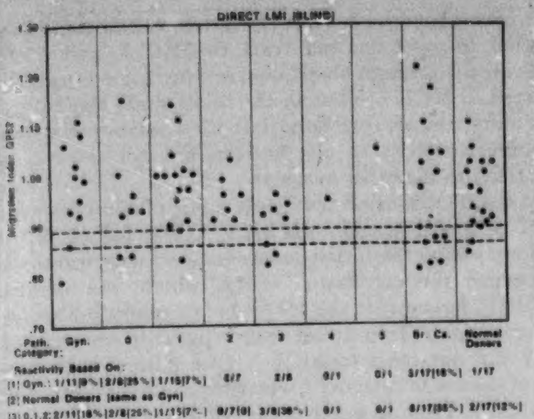
RESULTS

Direct LMI Assay With gp52 Antigen

Blind study.—The direct LMI assay was performed on 85 individuals by a technician who had no knowledge of the diagnosis of any of the individuals. One of us reevaluated the histologic slides of all the patients with benign breast disease without any knowledge of the test results. Text-figure 1 is a scattergram of the MI of the patients and controls and is based on the reevaluated pathology. By the Wilcoxon rank sum test, the MI of the patients with benign breast disease in category 3 were significantly different from those of the patients with gynecologic disorders ($P<0.04$) and the

---

[10] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.



TEXT-FIGURE 1.—Scattergram of MI of patients with gynecologic disorders, patients with benign breast disease in categories 0 through 5 (as described in "Materials and Methods"), breast cancer patients, and normal donors tested blindly with gp52 in the direct LMI assay. – – –, the cutoffs based on the normal donors or control patients with gynecologic disorders (*lower line*) or on the reactivity of patients with benign breast disease in categories 0, 1, or 2 (*upper line*). Along the *abscissa* are indicated the No. of individuals below each cutoff/total No. tested (% positive).

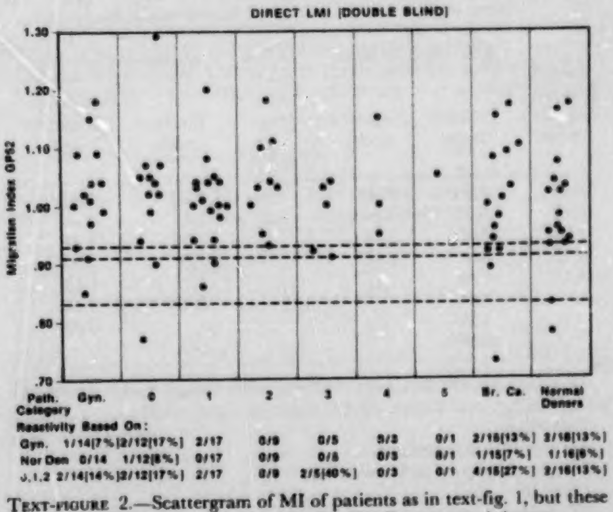
patients with benign breast disease in combined categories 0, 1, and 2 ($P<0.03$). None of the results obtained from the patients in the other groups were significantly different from those obtained from any of the control groups. The cutoff for the normal donors and the patients with gynecologic disorders was the same (0.86), and it was used to evaluate the proportion of reactive individuals among the patients with benign breast disease in the other categories. Breast cancer patient reactivity was 3 of 17 (18%) as compared to an overall reactivity of 5 of 40 (13%) among the patients with benign breast disease. Two of 8 (25%) patients with benign breast disease in categories 0 and 3 reacted as compared to 1 of 15 (7%) of the patients with benign breast disease in category 1 and none of the patients with benign breast disease in categories 2, 4, and 5. If the lower tenth percentile of the MI of the patients with combined categories 0, 1, and 2 benign breast disease with the least hyperplasia was used as a cutoff (0.89), 3 of 8 (38%) of the patients with benign breast disease in category 3 and 6 of 17 (35%) of the breast cancer patients reacted. None of these proportions were significantly different by chi-square analysis.

Double-blind study.—Another group of 102 individuals was assyed in the direct LMI test with the gp52 antigen, and the assay was performed double blindly; i.e., the technician performed the first part of the assay, and one of us drew the circles of migration and performed the planimetry measurements. Both individuals had no knowledge of the diagnosis of any of the test subjects. Again, the slides of the benign breast disease patients were reevaluated without any knowledge of the test results. The results are shown in text-figure 2. None of the groups were significantly different from each other when evaluated by the Wilcoxon rank sum test. Cutoffs of the 3 groups of controls were also used to evaluate the results. On the basis of the cutoff of 0.91 for the patients with gynecologic disorders, the normal donors' and the breast cancer patients' reactivities were similar (13%). Two of 12 (17%) patients with benign breast disease in category 0 and 2 of 17 patients with benign breast disease in category 1 were reactive, as compared to none of the patients with benign breast disease in categories 2, 3, 4, and 5. When an even more conservative cutoff (0.83) was set, based on the normal donor's reactivity, most individuals in all patient groups were unreactive or had very little reactivity (8% for patients with benign breast disease in category 1 and 7% for breast cancer patients). When the MI of the patients with benign breast disease in combined categories 0, 1, and 2 were used to set the cutoff (0.93), 2 of 5 of the patients with category 3 benign breast disease and 4 of 15 (27%) of the breast cancer patients reacted; however, 2 of 14 (14%) of the patients with gynecologic disorders and 2 of 16 (13%) of the normal donors reacted. None of these proportions differed by chi-square analysis.

Blind and double-blind studies combined.—If the results of blind studies were combined and analyzed relative to the benign breast disease (categories 0, 1, and 2) cutoff, 5 of 13 (38%) patients with benign breast disease in category 3 and 10 of 32 (31%) breast cancer patients reacted. By chi-square analysis, the reactivity of patients with benign breast disease in category 3 and the reactivity of the breast cancer patients were significantly different from the reactivities of patients with benign breast disease in categories 0, 1, and 2 ($P<0.05$), but neither differed significantly from the reactivities of the patients with gynecologic disorders or the normal donors.

Direct LMI Assay With MuMTV

Blind study.—Many of the individuals tested with gp52 were also tested with MuMTV. None of the groups differed significantly from each other by the Wilcoxon rank sum test. Again, the cutoffs for the normal donors and the patients with gynecologic disorders were more conservative (0.84 and 0.85, respectively), and only 4 of 44 (9%) benign breast disease patients reacted as compared to 3 of 21 (14%) breast cancer patients. With the cutoff for the patients with benign breast disease (categories 0, 1, and 2), 1 of 5 patients



TEXT-FIGURE 2.—Scattergram of MI of patients as in text-fig. 1, but these individuals were tested double blindly. Nor Don=normal donors.

with benign breast disease in category 3, 1 of 2 patients with benign breast disease in category 4, and 4 of 21 (19%) breast cancer patients reacted.

Double-blind study.—None of the groups reacted in the double-blind study with MuMTV with the use of any of the cutoffs. All groups were similar by the Wilcoxon rank sum test. Thus in this series of tests, the intact virus antigen did not discriminate preoperative breast cancer reactivity from that of any of the control groups.

Breast cancer reactivity to gp52 relative to histology of the breast tumors.—At least half of the reactive breast cancer patients had infiltrating lesions and at least one positive lymph node—4 of 6 in the blind study and 2 of 4 in the double-blind study (table 1). Among patients with invasive cancer but negative lymph nodes, only 1 of 4 in the blind study and 2 of 7 in the double-blind study reacted if the cutoffs for the patients with benign breast disease in categories 0, 1, and 2 were used for the evaluation. Only 1 of 7 patients with in situ lesions reacted. The patient with the highest index (1.21) had an in situ lesion associated with hyperplasia.

Direct LMI With gp52 and MCF-7 in Paired Experiments

Many patients tested with gp52 were tested simultaneously with MCF-7. The blind and double-blind tests were analyzed separately. The lower tenth percentile of MI for the patients with benign breast disease in categories 0, 1, and 2 combined was used as a cutoff for each antigen. These data are shown in text-figure 3 (A–C) and are summarized in table 2. In the blind study, the MI of all groups of patients were positively correlated to these two antigens but were only significantly correlated with MI of the normal individuals and the patients with benign breast disease in categories 0, 1, and 2 combined. Four of 6 breast cancer patients who reacted to gp52 did not react to MCF-7, and 1 of the patients with benign breast disease who reacted to gp52 also reacted to MCF-7. Thus in the blind study the MI to the two antigens were correlated, but often patients who showed positive reactivity to one antigen did not show positive reactivity to the other antigen.

In the double-blind tests, only a few patients tested with gp52 were also tested with MCF-7. The MI of all tested patients except the breast cancer patients were combined to determine the correlation index, which was significant ($P<0.01$). In contrast, the MI for breast cancer patients were not correlated. Two breast cancer patients who reacted to gp52 did not react to MCF-7. One patient with benign breast disease in category 1 who reacted to gp52 also reacted to MCF-7. Thus, in general, the MI of individuals tested in either the blind or double-blind studies were correlated, with the possible exception of those of the breast cancer patients.

Indirect LMI Assay With MuMTV Antigen

Migration inhibition.—The indirect LMI assay was performed on 213 individuals with MuMTV as the antigen, and three dilutions of the supernatants were tested for lymphokine. To evaluate the data for evidence of a migration inhibitory lymphokine, we compared the lowest indices obtained for each individual at any of the three dilutions among the various patient and control groups. As in the direct assay, all these blood samples were tested blindly. In addition, usually a different technician than the one who set up the assay and drew the circles measured the circles, so the test was usually double blind. Again, the histologic slides of all the patients with benign breast disease were reevaluated without any knowledge of the test results. Cutoffs were set at the lower tenth percentile of the same 3 groups of control individuals used in the direct LMI analysis. The least reactive control group was the patients with gynecologic disorders, and the cutoff based on their reactivity was 0.91. With this cutoff, 17 of 49 (35%) breast cancer patients, 35 of 83 (42%) benign breast disease patients, and 13 of 42 (30%) normal donors reacted. Patients with benign breast disease in categories 0, 1, and 4 were particularly reactive at 44, 48, and 67%, respectively. With the normal donors' MI used to calculate the cutoff, only 9 of 49 (18%) breast cancer patients reacted as compared to 8 of 25 patients with benign breast disease in category 0 and 11 of 33 (33%) patients with benign breast disease in category 1. When the MI of patients with benign breast disease in categories 0, 1, and 2 were combined to form the cutoff, the breast cancer reactivity was very low (6%). None of the groups differed from each other by the Wilcoxon rank sum test. Thus the indirect LMI assay with the MuMTV antigen failed to discriminate among the groups when the lowest MI were compared among the various groups.

Migration enhancement.—A lymphokine that causes enhanced migration of granulocytes has been described (*10*). Therefore, these same data were evaluated for the possible presence of such a lymphokine. To evaluate whether any test group had increased migration, we compared the high-

C) Assay was performed double blindly. Normal donors (●), breast cancer patients (▲), patients with gynecologic disorders (x), and patients with benign breast disease in categories 0 (○), 2 (■), and 3 (√).

TABLE 2.—*Simultaneous reactivity*[a] *to gp52 and MCF-7 based on blind tests*

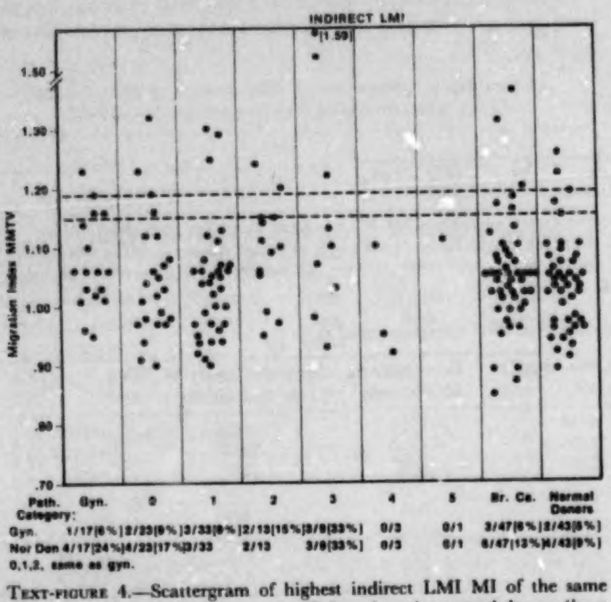
Individuals tested	Reactivity to both antigens[b]	Reactivity to gp52 only[b]	Reactivity to MCF-7 only[b]	Nonreactivity to both antigens[c]	r[d]
Breast cancer patients	2/16	4/16	2/16	8/16	+0.507
Normal females	0/30	3/30	4/30	23/30	+0.512[e]
Patients with gynecologic disorders	0/6	2/6	0/6	4/6	+0.577
Patients with benign breast disease					
Category 0	0/6	2/6	0/6	4/6	+0.661[e]
Category 1	0/13	1/13	1/13	11/13	+0.661[e]
Category 2	0/7	0/7	0/7	7/7	+0.661[e]
Category 3	0/7	2/7	0/7	5/7	+0.479

[a] Benign breast disease patients in categories 0, 1, and 2 were used to determine the cutoff.
[b] No. of persons reactive/total No. of persons tested.
[c] No. of persons nonreactive/total No. of persons tested.
[d] Correlation coefficient.
[e] $P<0.01$.

est MI of all three supernatant dilutions among the various patient and control groups (text-fig. 4). Cutoffs were set at the higher tenth percentile of the same 3 groups of control individuals used in the previous analysis. The cutoffs based on patients with gynecologic disorders or on patients with benign breast disease in categories 0, 1, and 2 were the same (1.19) (text-fig. 4). Category 3 benign breast disease, with the most hyperplasia, had the highest proportion of reactive patients (33%), and 2 of these patients had the two highest MI in the study—1.53 and 1.59. However, the proportion of reactive patients among patients with category 3 benign breast disease was not significantly different by chi-square analysis from that among patients with benign breast disease in combined categories 0, 1, and 2 or among the breast cancer patients. Similarly, none of the groups differed by the Wilcoxon rank sum test.

Breast cancer reactivity to MuMTV relative to histology of the breast tumors.—Lowest indices: Very few (4/49) of the breast cancer patients had infiltrating tumors and positive lymph nodes, and 50% of these were reactive. Twelve of 35 (34%) patients with infiltrating tumors and negative lymph nodes reacted as compared to 3 of 8 (38%) of those with in situ lesions.

Highest indices: all 3 patients who reacted had negative lymph nodes (table 3). Two of these had in situ lesions with hyperplasia and had quite high MI—1.31 and 1.36. Thus the lymphokine that facilitated migration seemed to be present in a high proportion of patients with hyperplasia—3 of 8 benign breast disease patients and 2 of 4 breast cancer patients. In fact, if the reactivity of the breast disease patients with hyperplasia (5/13) was compared to that of the breast disease patients without hyperplasia (8/104), the proportions were significantly different by chi-square analysis ($P<0.005$).



TEXT-FIGURE 4.—Scattergram of highest indirect LMI MI of the same patients as in text-fig. 1. – – –, cutoffs based on the normal donors (*lower line*) or on patients with gynecologic disorders (*upper line*) or patients with benign breast disease in categories 0, 1, and 2 (*upper line*). Along the *abscissa* are indicated the No. of individuals above each cutoff/total No. tested (% positive). Nor Don=normal donors.

Indirect LMI With MuMTV and MCF-7 in Paired Experiments

Lowest indices.—Many patients and controls were tested simultaneously with MuMTV and MCF-7. The relationship of the lowest MI with MuMTV and the lowest MI to MCF-7 in these paired experiments has been evaluated according to tests of normal individuals who had simultaneous results. A lower cutoff based on the lowest tenth percentile reactivity to these two antigens was set. Four of 6 breast cancer patients who reacted to MuMTV also reacted to MCF-7, and the MI of the simultaneous tests were significantly correlated, indicating that reactivity to two antigens was related when tested with the breast cancer patients. Among patients with benign breast disease in categories 0 and 1, a lower proportion who reacted to MuMTV also reacted to MCF-7—2 of 5 and 1 of 6, respectively. In patients with category 2 benign breast disease, both patients who reacted to MuMTV also reacted to MCF-7, and in the normal individuals all 3 patients who reacted to MuMTV did not react to MCF-7. The MCF-7 and MuMTV MI were not significantly correlated in any subject other than the breast cancer patients, and in benign breast disease of category 0 there was a negative correlation or discordance.

Highest indices.—The highest MI to MuMTV and MCF-7 in simultaneous tests were evaluated in text-figure 5 and summarized in table 4. The MI to the two antigens were correlated in all types of test individuals and significantly so in all but the patients with gynecologic disorders and patients with benign breast disease in category 2. At least half of the patients who reacted to MuMTV also reacted to MCF-7. Seven of 9 breast cancer patients who reacted to MCF-7 did not react to MuMTV. The 2 patients with

benign breast disease in category 3 and the 2 breast cancer patients who had very high MI to MuMTV also had high MI to MCF-7, indicating that the response to the viral antigen was similar to a response to a breast tumor-derived antigen.

DISCUSSION

The purpose of the present study was to evaluate whether the previously observed reactivity of MuMTV in breast cancer patients could be applied to breast cancer diagnosis (*5, 6*). In these previous studies, most of the patients were postoperative breast cancer or benign breast disease patients, and these studies were not performed blindly. About 65% of breast cancer patients reacted to gp52 in our laboratory, and 31% reacted to MuMMV-containing milk in the laboratory of Black et al. (*11*). The results obtained in the present study would appear to be in contrast to those of these previous studies in that 31% of the preoperative breast cancer patients reacted with the use of our least conservative cutoff. However, Zachrau et al. (*12*) tested preoperative breast cancer patients with gp55, and only 1 of 12 (8%) reacted. Their criterion for reactivity was an index of less than 0.80. By this conservative criterion, a similar proportion of breast cancer patients in our double-blind study reacted, i.e., 1 of 15 (7%). On the whole, the breast cancer patients' reactivities to gp52 and MuMTV were low among preoperative breast cancer patients, and their reactivities did not differ significantly from those of two sets of control patients (normal female hospital workers and preoperative patients with benign gynecologic diseases). Consequently, we do not believe that the direct or indirect LMI assays with the use of MuMTV antigens and peripheral blood can be useful for diagnosis of breast cancer.

However, there were differences in antigen preparation and assay technique in the experiments in Black's laboratory as compared to the preparation and technique used in our laboratory: 1) The gp55 was obtained by PAGE as compared to sequential ion-exchange and gel chromatography for the gp52 prepared by Dr. Parks; 2) the MuMMTV was obtained from mouse milk as compared to the supernatant from a mouse mammary tumor tissue-cultured cell line; 3) leukocytes were prepared by gravity sedimentation in the plasma and lysing of the erythrocytes with sodium chloride and distilled water as compared to gravity sedimentation in Plasmagel which augmented erythrocyte sedimentation; and 4) the assay was performed in Sykes Moore as compared to Sterilin chambers which are disposable.

The postoperative breast cancer reactivity to MuMTV was observed more frequently in women with in situ lesions than in women with invasive cancers (*11*). The incidence of reactivity that we observed previously was high in cancer patients without lymph node involvement (68% or 13/19) as compared to that in patients with invasive cancer with lymph nodes positive for tumor (45% or 5/11), except for women with invasive cancer who had been frequently skin tested with allogeneic breast-tumor-derived antigens (13/15, 87%) (Cannon GB, McCoy JL: Unpublished observations). In the present study with the direct and indirect tests, 33–50% of the patients with preoperative cancers with positive lymph nodes were reactive when the patients with benign breast disease in categories 0, 1, and 2 were used to determine the cutoff. The incidence of reactivity among the cancer patients with negative lymph nodes was lower—4 of 18 (22%) in the direct test and 15 of 43 (35%) in the indirect test.

One may speculate that the reactivity in the peripheral blood of patients harboring a tumor is different from that in the peripheral blood of postoperative patients who are relatively free of tumor. Possibly, the reactive lymphocytes are sequestered at the tumor site or otherwise inhibited, in stage I patients more than in stage II patients, and the pattern becomes reversed after mastectomy.

In our pathologic reevaluation of our preoperative benign breast disease patients, the category with the highest reactivity in the direct test and with the highest MI in the indirect test was category 3 in which the intraductal proliferation was either in the form of papillomatosis or hyperplasia. In retrospective studies involving reexamination of benign breast disease pathology, Black et al. (*13*) and Kodlin et al. (*14*) have shown a gradation of benign breast disease lesions, from normal to an atypia consistent with in situ carcinoma, to be related to an upward trend for breast cancer incidence. Davis et al. (*15*) reported that patients with epithelial hyperplasia developed mammary carcinoma 2.5 times as often as did the general female population, and patients with fibrocystic disease with no hyperplasia had 1.2 times the expected rate of mammary cancer. Monson et al. (*16*) have shown that women with chronic mastitis were at 2.5 times the risk of normal women for developing breast cancer and that this risk persisted for 30 years after biopsy. The association of reactivity to the viral antigens with the type of benign breast disease that is considered to be at high risk from pathologic evidence may provide some further insight into the biology of breast cancer.

A lymphokine that facilitates enhanced migration of leukocytes has been described by Weisbart et al. (*10*). It was produced by lymphocytes of PPD-sensitive donors in response to PPD. It was heat-stable, dialyzable, and distinct from leukocyte inhibitory factor by PAGE.

The ability of the indirect assay to measure a lymphokine that was measured by facilitation of normal donors' PMN cells to migrate was observed in 2 breast cancer patients with in situ carcinoma with hyperplasia, as well as in 3 benign breast disease patients with hyperplasia. This increased migration was also observed in 1 patient with breast cancer in situ with hyperplasia in the direct test. Previously, we have observed this increased or enhanced migration in first-degree relatives at high risk for melanoma and colon cancer in families with a high incidence of melanoma and colon cancer (Cannon GB, Dean JH, Greene MH, Blattner WA: Unpublished observations). These family members were tested in the direct agarose LMI test with melanoma-derived and colon cancer-derived extracts.

The increased or enhanced migration to MuMTV that we observed also occurred in simultaneous tests with MCF-7 as the antigen. Thus the antigens may be similar in these two materials and, in fact, MCF-7 has been implicated as containing a virus (*17*). Black et al. (*18*) have found correlations of LMI with gp55 and cryostats of in situ breast carcinomas and have suggested the immunologic relationship of these two materials. However, Zachrau et al. (*12*) did not find as much correlation in reactivity to MCF-7 and the in situ breast cryostats as they did with MCF-7 and gp55 or gp55 and the in situ breast cryostats in postoperative patients. They also found very low reactivity to both MuMTV and MCF-7 in preoperative patients.

Jenson et al. (*19*) have described a form of benign breast disease, characterized by atypical lobules, which was found more frequently in cancer-associated breasts (containing cancer or contralateral to cancer) than in breasts examined during random routine autopsies. The lesions showed variable degrees of epithelial hyperplasia, forming a gradation between normal epithelium and carcinoma in situ. Jenson et al. suggest that these lesions may be homologous to HAN that are abundant in mouse strains having a high incidence of mammary cancer. Wsi-zen et al. (*20*) have observed an increased or enhanced migration of macrophages in mice tested in LMI tests with cryostat sections of HAN that have formed tumors. They state that a substance produced by these early tumor cells may enhance macrophages or other inflammatory cells and drive them out of the area and suggest that the tumor would have a more favorable environment in which to develop. These authors attribute the enhanced migration to the tissue source, rather than to the leukocyte donor. However, the enhanced migration in patients with hyperplasia is interesting. These patients may have a tissue similar to the HAN present in their bodies at the time of the blood donation.

The identification of a subset of benign breast disease patients, who are at a higher risk pathologically with a functional immune response to MuMTV, seems to point to a possible association of virus recognition with early breast cancer.

Effect of Enzymatic Disaggregation on Proliferation of Human Tumor Cells in Soft Agar[1,2]

Anne W. Hamburger,[3] Christine P. White,[3] *and* Kathleen Tencer[3,4]

ABSTRACT—Cell suspensions were prepared by either mechanical or enzymatic disaggregation methods from biopsy specimens from 54 patients with various tumors. The biologic activities of cells derived from the two suspensions were then examined. Biopsy specimens of solid tumors were minced, and one-half of each specimen was further processed by being teased with needles, whereas the other half was exposed to a combination of collagenase, hyaluronidase, and DNase. The enzymatic disaggregation method yielded fewer cells per gram of tissue than the mechanical method. However, the percentage of dye-excluding cells was increased by the enzymatic procedure in 93% of the cases. Cells obtained by enzymatic means also had higher cloning efficiencies than those obtained by mincing. The histologic types of cells present in the initial cell suspensions were the same for cells obtained by the enzymatic or mechanical disaggregation methods. The number of colonies obtained was linearly related to the number of cells plated in both cases. The tritiated thymidine suicide indices (estimates of the percentage of cells in the S-phase of the cell cycle) were the same for the two cell populations obtained by the two methods. The results indicate that cells obtained from solid tumors by enzymatic dissociation methods did not differ significantly from cells obtained by the more conventional mechanical techniques. However, cell viabilities and cloning efficiencies were significantly improved by the enzymatic technique.—JNCI 1982; 68:945–949.

A method of cloning human tumor cells in soft agar has recently been developed (*1*, *2*). This technique appears to be suitable for culture of a variety of neoplasms of different histopathologies (*3*, *4*). The cell colonies retain many of the histologic, histochemical, functional, and immunologic properties of the tumor of origin. This system proved to be useful in elucidating biophysical and biologic properties of CFC from patients with a variety of neoplasms (*5*). This assay is also being used for testing of in vitro sensitivity of human tumor cells to anticancer drugs and for screening of new anticancer agents (*6*).

Cloning efficiencies of cells from many cancer patients are low in the soft agar system. In addition, only 25% of tumors yield enough cells to permit drug sensitivity testing (*7*). Improvements in disaggregating solid tumors should increase both cloning efficiencies and cell yield. We have previously used mechanical techniques to disrupt solid tumors (*1*, *3*), but the resultant debris, clumping, physical damage, and low yield resulted in suboptimal cloning efficiencies. Although collagenase has been reported to be effective in disrupting lung tumors, sarcomas, and melanomas (*8*), we sought a method that utilizes a combination of enzymes to maximize cell yields for many tumor types.

Enzymatic disaggregation techniques may cause subtle, hard-to-control changes in cells, such as membrane alterations, protein loss, altered metabolism, and changes in antigenicity and drug sensitivity (*9*–*12*). It is therefore of utmost importance to compare rigorously the biologic activities of cells obtained by either mechanical or enzymatic means from the same tumor. We have found that a combination of enzymes enhanced cloning efficiencies of tumor cells without changing several other biologic properties. The results of this study indicate that cells obtained by enzymatic dissociation techniques from solid tumors are acceptable for use in agar cloning assays.

MATERIALS AND METHODS

Collection and treatment of cells.—Tumor cells were obtained from biopsy specimens of solid tumors from 54 patients with various neoplasms. The cancerous nature of the specimens was confirmed by a clinical pathologist. Appropriate informed consent was obtained from all the patients. We obtained tumor nodules after surgery and removed all fat and necrotic and connective tissues. The tumors were then cut into two pieces of approximately equal size and similar gross morphology and were weighed. One piece of each tumor was disaggregated mechanically, and the other piece was disaggregated enzymatically. Mechanically dissociated tumors were minced with scalpels and teased apart with 22-gauge needles. Cells released into the media were filtered through 22-μm Nitex gauze for removal of cell clumps and were washed twice in HBSS (GIBCO, Grand Island, N.Y.) with 10% heat-inactivated FCS (Reheis Chemical Co., Kankakee, Ill.). Viable nucleated cell counts were determined in a hemacytometer with the use of erythrosin B. The second piece of tumor tissue was similarly minced into 3- to 6-mm pieces and then removed to a 25-ml trypsinizing flask and resuspended in enzyme solution. We used various combinations and sequences of enzymes initially, and later we used the following mixture: Approximately 1 g of tissue was resuspended in 7 ml collagenase (1,800 U/ml collagenase type I; Sigma Chemical Co., St. Louis, Mo.), 7 ml hyaluronidase (type I 1,220 U/ml; Sigma Chemical Co.), and 0.02% DNase (38,800 Kunitz U/mg protein). All the enzymes were prepared in HBSS and stored in aliquots at −40°C. Tissue pieces were incubated in a shaking water

bath at 37°C for 1.5–3 hours. We stopped treatment when only a few pieces of tissue were left in the suspension. Cells freed from the tissues were washed and filtered as described for mechanically released cells. We performed differential counts on slides prepared with a cytocentrifuge and stained by the Papanicolaou (*13*) and Wright-Giemsa methods and we assayed for nonspecific esterase-activity (*14*).

Culture assay for CFC.—Cells were cultured as described by us earlier (*1*, *2*). Underlayers (1 ml), containing enriched McCoy's 5-A medium in 0.5% Bacto-agar (Difco Laboratories, Detroit, Mich.), were prepared in plastic petri dishes 35 mm in diameter. Conditioned medium was not included. Cells to be tested were suspended in 0.3% agar in enriched CMRL 1066 medium (GIBCO) with 15% horse serum (Flow Laboratories Inc., Springfield, Va.). Each culture received 5×10^5 cells in 1 ml of agar–medium mixture. Cultures were incubated at 37°C in a humidified incubator with a 7.5% CO_2 atmosphere.

Scoring of cultures.—Cultures were examined with a Zeiss inverted-phase microscope at 100 and 160× magnification for the presence of clumps immediately after plating, and those containing clumps were discarded. Final colony counts of coded plates were made between 10 and 21 days after plating; aggregates of 30 cells or more were considered colonies. The 0.3% agar layer that contained the colonies was fixed and dried onto microscope slides as described (*15*). Slides were stained with Papanicolaou stain for examination of morphology. The presence of peroxidase, nonspecific esterase, and periodic acid–Schiff and mucicarmine reactivities was also determined (*13*, *14*).

Determination of the proportion of cells in DNA synthesis by [^{3}H]dThd suicide test.—The [^{3}H]dThd suicide method was used for estimation of the proportion of CFC in the DNA synthetic S-phase of the cell cycle (*16*). Samples of 2×10^6 cells suspended in HBSS and 10% heat-inactivated, dialyzed FCS were added to 1.0 ml of HBSS containing 40 μCi of [^{3}H]- dThd (23 Ci/mmol; Amersham/Searle Corp., Arlington Heights Ill.). Control samples were added to HBSS alone. Cell suspensions were incubated for 30 minutes at 37°C and washed twice with 20 ml of cold HBSS containing 100 μg unlabeled thymidine/ml and 10% FCS. Each suicide and control suspension was cultured in four replicate plates at a concentration of 5×10^5 cells per plate.

Statistical analysis.—Statistical significance of the differences between samples was determined by Student's *t*-test. Four or five plates were scored per point. The effect of each disaggregation method on each dependent variable, such as percentage of dye-excluding cells, was determined by a two-way analysis of variance. Statistical significance was determined at the 5% level.

RESULTS

Cell yields.—The total number of cells released from tumor specimens by either mechanical or enzymatic means was extremely variable for all tumor types (table 1). However, the median yields of cells obtained by mechanical procedures were greater than the median yields obtained by enzymatic procedures for breast, colon, and kidney tumors. The median cell yields by the two methods were not significantly different for lung or ovarian tumors or for melanomas.

Proportion of viable cells.—The percentage of dye-excluding cells was variable for all disease types (table 1). In general, the proportion of viable cells obtained by enzymatic methods was higher than that obtained by mechanical methods for all disease types except melanoma. The median yield of viable cells per gram of tissue was slightly greater when ovarian, lung, and kidney tumors were enzymatically dissociated and slightly lower when colon or melanoma tumors were enzymatically dissociated compared to the yields of mechanical disaggregation.

Clonogenicity.—Cloning efficiencies were variable within the same disease type (table 1). However, the median cloning efficiencies of cells released enzymatically from tumors of all disease types tested was higher than that of the mechanically released cells. Neither the kinetics of colony growth nor the size of individual colonies formed was consistently different

[b] Percentages of cell types for each tumor were based on two slides, 500 cells/slide.

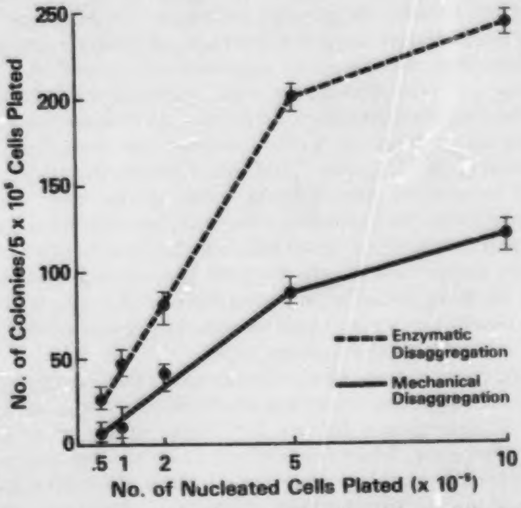
for cells obtained by enzymatic or mechanical dissociation techniques.

There was considerable heterogeneity in cloning efficiencies, cell viabilities, and cell yields for the group as a whole. Due to the large variability in the data, and the relatively small number of samples in different disease categories, differences between cells derived by enzymatic means and those derived by mincing were often of borderline significance. However, for all disease types, cloning efficiencies of cells prepared enzymatically were greater than cloning efficiencies of cells obtained by mincing from the same tumor in 28 cases. No differences in cloning efficiencies of cells obtained by the two methods were observed in 14 instances. In only 3 cases were cloning efficiencies of cells derived from minced tissue greater than cloning efficiencies of cells obtained enzymatically from the same tumor. Similarly, the percentage of viable cells obtained enzymatically was greater than the percentage of viable cells obtained mechanically from the same tumor in 42 cases. In only 3 cases was the percentage of viable cells observed greater from mechanically dissociated cells than from enzymatically dissociated cells from the same tumor. In 27 cases, more cells were obtained per gram of tissue from the same tumor by mechanical methods. In 20 cases, more cells were obtained enzymatically. In 25 cases the yield of viable cells per gram of tissue was greater when enzymatic dissociation methods were used. In 6 cases no differences in yields of viable cells were observed. In 15 cases, the yield of viable cells per gram of tissue was greater when mechanical methods were used compared to that obtained by the enzymatic method.

Cytology of released cells.—To determine if mechanical and enzymatic procedures released morphologically different populations of cells, we examined the cytologic profile of the suspensions (table 2). Tumor cells comprised the majority of cells for all disease categories as determined by morphologic analysis. There were no significant differences in the median numbers of tumor cells from suspensions obtained by either mechanical or enzymatic methods. Variable and low numbers of macrophages, lymphocytes, and granulocytes were observed. We did not observe any difference in the number of cell types between enzymatically or mechanically prepared cell suspensions.

Relationship between number of cells plated and colony formation.—Text-figure 1 shows the relationship between the number of cells plated and the number of colonies formed from cells obtained from a patient with adenocarcinoma of the colon. The results from 3 other patients with adenocarcinoma of the colon, lung, and breast were qualitatively similar, although the actual number of colonies varied. A linear relationship was observed between the number of nucleated cells plated (up to 5×10^5 cells) and the number of colonies formed among cells obtained by either mechanical or enzymatic methods. The nonlinearity observed above 5×10^5 cells per plate may have been due to depletion of nutrients or to the toxic effects of cell crowding. However, significantly more colonies were formed at each cell concentration tested when cells were obtained by enzymatic methods.

Proliferative state of tumor cells obtained by different disaggregation methods.—Because enzymatic treatment of tumor cells may alter the cell cycle properties (*17*, *18*), we examined whether



TEXT-FIGURE 1.—Relationship between colony formation and the number of nucleated cells plated. Pieces of a tumor from a patient with adenocarcinoma of the colon were disaggregated by either enzymatic or mechanical methods, and the cells were plated at the concentrations indicated.

the number of cells in the S-phase of the cell cycle was different for cells obtained by either enzymatic or mechanical means. Incubation of cells with high-specific-activity [^{3}H]dThd decreased colony formation in 5 cases and increased colony formation in 2 cases (table 3). The survival of CFC obtained by enzymatic means was not significantly different than that observed with cells obtained by mechanical disruption.

DISCUSSION

The mechanical disaggregation methods routinely used to produce cell suspensions for clonogenic assays of human tumor cells do not yield large numbers of viable cells, and cloning efficiencies are often low. An enzymatic disaggregation technique that would increase both cell yield and cloning efficiency would be desirable. However, before a new disaggregation procedure is employed, it is necessary to compare it with the proven technique to determine the similarity between the cell suspensions. We therefore divided tumors into two pieces of approximately equal size and similar gross morphology for direct comparison of the effect of the two disaggregation methods on the same tumor. A potential problem with this approach has been noted by Slocum et al. (*17*), who found that cloning efficiencies may vary in anatomically different parts of the same tumor. Cowan et al. (*18*), however, observed that cells from different parts of the same tumor have similar cloning efficiencies. Direct comparison of cells from the same tumor may therefore be more useful than comparison of the effects of the two disaggregation methods on separate groups of different tumors of the same histologic type.

The heterogeneity of our data makes it difficult to predict whether enzymatic treatment would be superior to mechanical disaggregation for an individual tumor of a given histologic type. More samples would be needed to predict with greater certainty the optimal method for disaggregation of an individual tumor. In general, enzymatic procedures appeared superior for all tumor types tested except for melanoma. For example, the fraction of cells able to exclude dye was significantly greater for the enzymatically released suspensions in 42 of 45 tumors tested. In addition, a slightly greater yield of viable cells per gram of tissue was noted for lung, ovarian, and kidney tumors. We have found that it is preferable to work with cell suspensions of high viability, and that cell suspensions that contain large numbers of dead cells and debris do not grow well (*3*). Theoretically, it is possible to remove dead cells from mechanically prepared suspensions. Our attempts to selectively remove dead cells by centrifugation through FCS, Ficoll-Hypaque, or Percoll have not significantly enriched the suspensions for viable cells. Slocum et al. (*19*) reported similar results.

Cloning efficiency provides a more useful estimate of the cells' proliferative ability than does dye exclusion. Cloning efficiencies of tumor cells obtained by enzymatic treatment were equal to or greater than that observed for mechanically disaggregated cells in 42 of 45 cases. These data agree with those in an initial report by Pavelic et al. (*8*) but vary from their later report for lung tumors and melanoma (*19*). Our number of cases for these disease types is small, and it is possible that in a larger population significant differences would not be observed. Because cloning efficiencies of tumor cells were significantly increased in cell suspensions obtained by enzymatic means, this method may be of use to investigators studying biologic properties or drug sensitivities of CFC.

The two dispersion methods may release different populations of cells. Tumors contain many nontumor cells, including macrophages and lymphocytes. We have shown that macrophages influence survival of clonogenic cells (*3*). Morphologic and histochemical analyses did not indicate significant differences in the cytologic profile of cells obtained by the two dissociation methods. The low percentage of tumor-infiltrating macrophages observed in these studies differs from the findings of Gauci and Alexander (*20*). They observed that the macrophage content of tumors ranged from 0 to 30%, although the majority of tumors contained less than 10% macrophages. However, our results are similar to those reported by Slocum et al. (*19*), who found a median of 7% macrophage-monocytes in their preparations. These differences may be due to the fact that the method of Gauci and Alexander (*20*) involved the use of a macrophage-specific heteroantibody rather than the histochemical method used in this study.

Enzyme treatment may also alter the cycling characteristics of tumor cells (*21, 22*). We estimated the proportion of cells in the S-phase of the cell cycle by [^{3}H]dThd suicide techniques. The fraction of cells in the S-phase was not significantly different for cells obtained by the two methods from the same patient. The increase in colony formation in 2 cases observed after exposure to [^{3}H]dThd has been observed previously (*3*), and it may relate to recruitment of clonogenic cells from a G_0 state to a cycling state. However, the effects of cell cycle-specific drugs on CFC obtained by the two disaggregation techniques should not be significantly different because the suicide indices were not significantly different.

In summary, both the viabilities and the cloning efficiencies of cells obtained by enzymatic methods were higher than those of cells obtained by mechanical disaggregation. Neither the cytologic profile nor the fraction of cells in the

S-phase of the cell cycle was significantly different for cells obtained from the same patient by the two methods. The results indicate that the enzymatic procedure did not damage the functional activity of tumor cells. Preliminary experience with drug tests in cells from a small number of patients suggests that cells obtained by enzymatic procedures may be useful in the study of drug sensitivities of clonogenic cells. Data on many patients are required to verify this result. In addition, clinical observations must be made to determine if cells obtained enzymatically may be used for prediction of the patient's clinical response.

Diverse Xenotropic Virus Expressions in Two NZB Mouse Breeding Lines That Differ in Chromosome Breakage[1, 2]

Carmen Bernard[3] *and* Ingrid Emerit[4, 5]

ABSTRACT—Two breeding lines of the NZB/Bl mouse strain, which was originated from Bielschowsky's stock and maintained as a conventional inbred colony since 1963, were developed by selective matings according to chromosome breakage incidence in bone marrow cells. These breeding lines were used because they represent an interesting experimental model, since they differ in the manifestations of the autoimmune process and the incidence of lymphomas. The present study showed that embryos from both breeding lines differed in the expression of the xenotropic type C RNA virus, characteristic of NZB mice. All 17 cultures initiated with embryos from the line showing high chromosome breakage (HB) had positive reverse transcriptase (RT) reactions after cocultivation with an indicator cell line (SIRC). On the contrary, only 3 of the 22 embryos from the line showing low chromosome breakage (LB) had RT activity at late passages (7–10). The chromosome studies done on these embryo cultures showed highly significant differences in the chromosome breakage incidence for the 2 breeding lines [10.6 and 20.5% of cells with aberrations for LB and HB embryos, respectively ($P<0.001$)].—JNCI 1982; 68:951–958.

NZB mice spontaneously develop an autoimmune syndrome similar to human lupus erythematosus with immune complex nephritis and antinuclear and antinucleic acid antibodies, as well as Coombs' positive hemolytic anemia. If the mice do not succumb to the nephritis and anemia, they frequently die of lymphoid neoplasia of the immunoblastic type (*1*). In 1972, we demonstrated an important increase in chromosomal breakages in bone marrow cells from NZB mice of our strain (*2*). Other colonies have mosaicism for spleen cell euploidy and aneuploidy involving specific chromosomes (*3–5*). The chromosome instability is correlated with the presence of a clastogenic agent in the sera of these mice (*6*). By selective matings founded on chromosome breakage frequencies in bone marrow, 2 NZB lines could be developed: an HB line and an LB line (*7*). Comparative studies of HB and LB mice showed significant differences in the incidence of lymphomas and other neoplasias. The conversion of the Coombs' test was also significantly more frequent and occurred earlier in HB mice than in LB mice (*7*). The data of the present study indicate that the 2 NZB lines differ also in endogenous virus expression.

MATERIALS AND METHODS

Animals.—The NZB/Bl mouse strain originated from Bielschowsky's stock and had been maintained as a conventional inbred colony in Paris since 1963. From the selection period on, the animals were no longer bred by brother × sister matings but between litters so as to assure the mating of extremes. Animals with chromosome breakage figures under 10% are LB animals; those with chromosome breakage figures over 30% are HB animals. Both percentages are statistically different for 50 mitoses studied. The proportion of LB and HB animals in the 2 breeding lines, developed by selective matings according to chromosome breakage incidences in bone marrow cells, is shown in table 1. Since the cytogenetic study of generation F7 of the LB line has shown normal values in 98% of the females, the chromosome breakage incidence of the females was not controlled before the mating from generation 8 on. In 14.3% of the males, increased chromosome breakage had to be expected (table 1) and for this reason the breakage rate was established for all males used for the continuation of the LB line. The 4 males used for the production of the LB litters had chromosome breakage figures between 0 and 6.3%. The animals belonged to filial generations 7–10 and were 5–7 months old when they were mated. Three litters from HB parents and 4 litters from LB parents were delivered by cesarean section at days 16–17 of gestation. The LB litters consisted of 9, 10, and 8 embryos (litters 1, 2, and 4, respectively), except for litter 3 consisting only of 3 embryos, from which 1 did not give successful cultures. The number of fetuses in the 3 HB litters was 8, 10, and 12, respectively, from which 6 were taken at random for the cultures.

Cell cultures.—Primary cell cultures were derived by trypsinization from single embryos after removal of the head, limbs, tail, and abdominal organs. The cells were grown in RPMI-1620 medium supplemented with 20% heat-inactivated fetal bovine serum containing antibiotics. When confluent, each monolayer was transferred by treatment with 0.25% trypsin. Passages of embryonic fibroblasts were done at 5-day intervals.

To enhance potential recovery of endogenous xenotropic virus, we cocultivated embryonic cells with susceptible heterologous cells. At the first passage of embryonic cells, one of the cultures was grown in the presence of rabbit corneal

[a] The figures represent percentages of animals in the 2 populations: For the LB line this proportion increased from 28.6 to 85.7%; for the HB line, the proportion of animals with HB figures could not be increased beyond generation 5. *Dash* indicates not done.

cell lines SIRC. These cocultures were done at a ratio of 3×10^6 NZB embryonic cells to 10^6 SIRC cells and were transferred at a split ratio of 2:1 every 2d day.

Virologic studies.—a) RT assays: The cocultures between NZB and SIRC cells were checked for the presence of extracellular C-type viruses by RT assay performed on the culture fluids.

Medium from each tissue culture was clarified by centrifugation at 10,000×*g* for 10 minutes. Of the clarified supernatant, 15 ml was then loaded onto an 8-ml cushion of 20% glycerol in 0.05 *M* Tris-HCl (pH 8) and 0.10 *M* NaCl and spun at 105,000×*g* for 90 minutes at 4°C. The viral pellet was resuspended in 50 µl of the above buffer containing 1 m*M* 1,4-dithiothreitol and 0.1% Triton X-100 or 0.05% Nonidet P40. Of this virus suspension, 20 µl was added to 50 µl of a reaction mixture containing 50 m*M* Tris-HCl (pH 8), 50 m*M* KCl, 0.5 m*M* $MnCl_2$, 1 m*M* 1,4-dithiothreitol, 0.04 A_{260} U of polydeoxyadenylate:deoxythymidylate (12:18), and 3×10^{-6} *M* [^{3}H]TTP (sp act, 40–50 Ci/mmol). After 30 minutes' incubation at 37°C, the reaction was arrested with chilled saturated pyrophosphate and 10% TCA. The acid-precipitable fractions were collected on Millipore membranes (450 nm), washed with 5% TCA, and enumerated in a Packard liquid scintillation counter. Twenty microliters of pelleted virus used in the reaction mixture corresponded to virus produced by 2×10^6 cocultured cells: results were considered negative when about 0.2 pmol of [^{3}H]dTMP (<10,000 cpm) was incorporated into acid-precipitable nucleotides.

b) Determination of host range: The virus particles recovered by ultracentrifugation from the cocultures of HB embryos were inoculated onto mouse cells of the N- or B-type to determine whether the virus from our strain has a xenotropic host range as described by Levy and Pincus (*8*).

Chromosome studies.—The chromosome analysis for the establishment of the chromosome breakage incidence in the parent animals was done on bone marrow cells. The mitoses were arrested in metaphase by ip injection of 0.01 ml colchicine/g body weight (0.24% solution), 2 hours before one femur bone was removed from the animal under general anesthesia. The bone marrow was washed out of the femur with a syringe and needle. After hypotonic pretreatment (75 m*M* KCl) for 20 minutes, the cells were fixed in ethyl alcohol to glacial acetic acid at 3:1. Slides were air dried and stained with Giemsa. The chromosomes were scored for aberrations under the microscope on coded slides. Gaps and breaks of one or both chromatids, acentric fragments, dots, and structurally rearranged chromosomes were noted. The aberration rate was calculated from a total of 50 mitoses.

For chromosome studies in fibroblast cultures from NZB embryos, colchicine was added to the culture medium after a cultivation of 24 hours for the last 3 hours. The cultures were studied at passage 1 or 2. After trypsinization, the cells were exposed to the same procedure as described above for bone marrow, except that iced wet slides were used for spreading of the mitoses instead of dry slides prewarmed in a flame.

RESULTS

Host range of virus.—The virus recovered by ultracentrifugation from the cocultures was not infectious for mouse cells but grew readily in a mink cell line, thus indicating a xenotropic host range. This experiment was done with virus particles from three different cocultures.

Virus production.—As seen from table 2, the virus assays in the culture media from 17 cocultures of NZB/Hb embryos were positive from the fourth subcultivation on. In 3 embryos, positive results were obtained even at passage 2. The enzyme levels reached very high titers from passage 4 on, and in 7 of the 17 embryos the RT values measured were higher than 20 pmol of incorporated [^{3}H]dTMP/2×10^6 cocultivated cells.

Among the 22 embryos from the NZB/Lb substrain, only 3 had positive RT reactions at late passages (7–10). Two of these belonged to litter 2 that differed from the 3 other litters by the low number of fetuses. The RT levels did not exceed 0.5 pmol of [^{3}H]dTMP incorporation.

Chromosome studies.—Chromosome analysis could be done in 21 of the 22 LB embryo cultures. In embryo #5 the number of mitoses available was too low. No increase in the aberration rate was found in 10 embryo cultures (47.6%); the remaining had "intermediate" breakage frequencies (11–29%). No LB embryo had HB aberration rates i.e., higher than 30%.

The proportion of animals with normal and intermediate breakage rates varied according to litters. In 1 litter, all fetuses had normal values. This litter was derived from the male with the lowest aberration rate (0%) and belonged to filial generation 10.

In 4 of the 17 HB embryo cultures, chromosome analysis could not be done because of lack of mitoses. Among the 13 cultures studied, 3 had aberration rates higher than 30%, 8 had intermediate breakage figures, and only 2 had normal values.

The mean of mitoses with aberrations was 10.6% for LB

embryo cultures and 20.5% for HB embryo cultures ($P<0.001$). The total of aberrations per 100 cells also differed significantly for LB and HB embryo cultures (14.1 and 25.0%, respectively).

The aberrations consisted of gaps and breaks of one or both chromatids, telomeric extrusions, fragments, dots, exchange figures, and structurally rearranged chromosomes. Pulverization of single chromosomes and fragmentation of the whole metaphase plate as described previously (*6*) were observed in HB embryo cultures.

DISCUSSION

Increased chromosome breakage and rearrangement are observed in fibroblast cultures from NZB embryos (*5, 9*) and in "direct" chromosome preparations from bone marrow cells of adult NZB mice (*2*). This chromosome breakage characteristic could be used as the basis of a selection experiment that resulted in the separation of a line with LB incidence. The proportion of animals with HB and LB rates in the progeny depended on the phenotype of the parents (*7*). Comparative studies of the 2 lines showed that the selection on the basis of chromosome breakage rates had influenced also the pathologic manifestations of the NZB mouse disease. Malignant lymphomas occurred in 14.1% of NZB mice from the HB line, while the incidence was only 4.2% in the LB line ($P<0.01$). The conversion of the Coombs' test was also significantly different for both breeding lines. From the HB line 60% of males and nearly 70% of females were Coombs' test-positive at the age of 6 months compared to only 3–4% of the LB mice. The data of the present study show also significant differences for the expression of the xenotropic type C RNA virus of NZB mice (*8*).

The enzyme RT is common to all mammalian type C RNA viruses. These viruses need RT for their integration in the genome of the host as DNA provirus. NZB embryo cultures usually do not yield this enzyme at detectable levels, and cocultivation with susceptible cells is necessary to enhance the possibility of detecting low levels of virus production. This finding was also the case in the present study, in which an SIRC cell line was used as an indicator. All embryo cultures from the HB line gave positive RT assays of high titer. The virus recovered by ultracentrifugation of the cocultures was shown to have a xenotropic host range similar to that of the virus described by Levy and Pincus (*8*) in their NZB colony. A treatment with 5-iodo-2′-deoxyuridine for eventual induction of an NZB-X2, as described by Elder et al. (*10*), was not done either in HB or in LB cells. Only 3 of the 22 cocultures initiated from embryos of the LB line displayed enzyme activity at late passages. Of these 3 embryos, 2 were unique since they belonged to litter 2 with only 3 fetuses. We may conclude that the selection has also influenced the virus production and that the LB line releases only exceptionally the NZB virus at detectable levels. More sensitive assays might give positive results for the presence of the NZB virus. This possibility does not preclude the interest of this study in the intention to show differences between the 2 breeding lines. That these differences in virus expression exist could be shown in a significant way.

NZB mice are supposed to lack normal restriction of complete xenotropic virus expression and to release spontaneously this endogenous virus. Two independently segregating autosomal dominant genes (*11*) or rather one single autosomal dominant gene (*12*, *13*) is involved in the genetic regulation of virus expression. The results of studies on reciprocal crosses and back-crosses between animals of both breeding lines agree with regard to the dominance of the breakage characteristic and these studies reach the same conclusion as the studies on virus expression (*14*). Mutation at virus suppressor loci was suggested as the cause for the spontaneous virus release in NZB mice (*11*). Thus, beside the possibility of having selected a line on the basis of virus infectivity, selection based on virus restriction has to be considered.

In general there was a good correlation between virus recovery and chromosome aberration rate. The earliest RT assays were observed for litter 5, which was comprised also of the 3 embryos with the highest aberration rates and 2 cultures of bad growth. Litter 6, comprised of 2 embryos with normal and 2 embryos with near-normal values (12.1 and 12.5%, respectively), gave positive results only in later passages not exceeding 50,000 cpm. Possibly, the 2 embryos from litter 6 with normal cytogenetic results (9.1 and 6.3%) would have shown higher aberration rates at later passages when the RT assays became positive. The discrepancy between considerably increased breakage rates and negative RT assays in 2 of the LB embryos (#4 and 13) is more difficult to explain, but the number of discordant results is too small to change the conclusion.

Damaging properties of both DNA and RNA viruses to the chromosomes are well known [*for review see* Nichols (*15*)]. The effect of the avian oncoviruses in mammalian systems has been intensively studied. Using rat fibroblasts, Nichols and co-workers (*16*) found chromosome aberrations after the cells were infected with RSV. Increased breakage was also observed by Kato (*17*) with RSV in Chinese hamster cells. Chromosome abnormalities were regularly observed in sarcomas induced by RSV (*18*, *19*) and the type of aberrations, especially minute fragments and "pulverizations," is quite similar to that observed in the NZB cultures.

If a causal relationship between chromosome damage and virus release is presumed, the question remains whether the virus is also responsible for the development of tumors and autoimmune reactions. The oncogenic properties of xenotropic viruses are not confirmed, and recent evidence suggests that most endogenous type C viruses are not transforming agents but are inherited in the host to function in other biologic processes (*20*). Autoimmune reactions were found to be independent of xenotropic virus in the NZB mice studied by Datta and Schwartz (*11*).

Another possibility would be that the chromosome aberrations themselves, secondary to somatic mutation, are responsible for the development of cancer and autoimmune reactions in this strain. The eventual role of chromosome instability at the origin of cancer and abnormal immune reactions has been proposed already by other authors (*21*, *22*).

Further work is necessary for a better understanding of the interrelationship between viruses, chromosome damage, and pathologic manifestations of NZB mouse disease. The 2 NZB mouse breeding lines differing in these parameters may be useful as an experimental model.

Phenotypic Stability of Murine Tumor Cells In Vitro and In Vivo[1,2,3]

James Varani[4] *and* **Edmund J. Lovett**[4]

ABSTRACT—Murine fibrosarcoma cells that vary in their transplantability in syngeneic mice were isolated from a heterogeneous parent tumor (induced in a female C57BL/6 inbred mouse) and maintained in culture by serial passage. Several biologic properties that discriminate between the high- and low-transplantable lines (including adhesiveness, motility, and levels [illegible] chymotrypsin-like esterase activity), as well as properties that do not separate these lines (e.g., in vitro growth rates and levels of protease and glycosidase activities), were measured at periodic intervals over 2 years. Ability to induce primary tumors and to induce metastases from these tumors were evaluated at the same intervals. The high- and low-transplantable lines were also transplanted into syngeneic mice at tumorigenic doses. Isolates from primary and metastatic tumors induced in the animals were reestablished in culture and examined for the various characteristics at passages 5, 10, 20, and 30. The properties of the cells maintained continually in culture remained stable throughout the 2-year observation period. Tumor isolates showed some evidence of modulation immediately after reestablishment in culture, but by passage 10 they appeared to be identical to the prototype parent lines. These data show that the fibrosarcoma cells do not undergo continual phenotypic "drift" as has been suggested to occur with other tumor lines maintained by serial passage in animals or in culture.—JNCI 1982; 68:957–962.

Recent investigations in several laboratories have revealed that uncloned tumors are heterogeneous entities comprised of several distinct subpopulations (*1–7*). Many of these heterogeneous tumors are being used in efforts to determine which of their properties contribute to cancer. It is essential, therefore, to determine exactly how stable these tumor populations are, particularly since many phenotypic alterations are known to occur in tumor cells maintained in culture or in animals over a long period of time (*8–12*). The only way that the stability of particular cell populations can be verified is by maintaining the cells in culture or in animals for extended periods and examining them periodically with regard to specific characteristics. This report addresses the question of tumor cell stability in one model system.

MATERIALS AND METHODS

Tumor cells.—Two populations of fibrosarcoma cells isolated from a 3-methylcholanthrene-induced tumor in a female C57BL/6 inbred mouse (The Jackson Laboratory, Bar Harbor, Maine) were used in this study. These two populations represent prototype "high-transplantable" and "low-transplantable" lines of cells. A description of the isolation procedures used to obtain these cells has been presented in our recent reports (*6, 7*). A number of additional lines with characteristics similar to those of these prototype lines have also been isolated (*6, 7, 13–15*).

The prototype high-transplantable line was isolated from a pulmonary metastasis in a C57BL/6 mouse that was given an injection of 1×10^5 parent cells in the right rear footpad 30 days earlier. The prototype low-transplantable line was isolated from the parent cells by adapting the cells to grow in medium supplemented with 10% normal human serum in place of 10% FCS. After passage of the cells in human serum-containing medium for 3 months, they were returned to medium with FCS and maintained ever since. After establishment in culture, both lines were cloned. Cloning was accomplished by seeding dishes 35 mm in diameter with small numbers of cells (≈100 cells/dish) and by isolating individual colonies by scraping with a glass needle. Colonies isolated in this manner were subcloned two additional times in the same manner. The cells were then diluted and added to microtiter wells in 50-μl volumes. The wells were subsequently examined under phase-contrast microscopy, and those wells containing only a single colony were noted. The cells harvested from such wells were assumed to be clonally derived.

In addition to the two prototype lines, six isolates were established in culture from primary tumors or metastatic tumors that developed in syngeneic mice after injection with either of the two prototype lines. After establishment in culture, the six isolates as well as the two prototype lines were maintained under identical conditions which included growth on medium 199 supplemented with 10% FCS. We purchased the cell culture media and the reagents used throughout this study from GIBCO, Grand Island, N.Y. FCS was obtained from the Kansas City Biological Co., Lenexa, Kans. We used cell culture plastic ware from a number of commercial sources; none of them proved to be superior to the others. The cells were grown at 37°C in 5% CO_2 atmosphere. All cell lines were determined to be free of mycoplasma contamination by culture on mycoplasma agar and in mycoplasma broth.

Experimental protocol.—The two prototype lines were established simultaneously between January and May 1977 and were maintained by serial passage in culture. They were subcultured at a 1:4 split ratio on a 3- to 5-day schedule. Each line was periodically examined with regard to several biologic properties over the ensuing 2 years. On two occasions (at ≈1 yr and 1.5 yr after the start of the experiment) cells of each line were removed from the freezer and compared with the cells maintained in culture. The tumor isolates were also maintained in culture by serial passage and examined at passages 5, 10, 20, and 30.

Abbreviation used: FCS=fetal calf serum.

[3] Animals were maintained under the guidelines set forth by the University of Michigan.

[4] Department of Pathology, The University of Michigan Medical School, Box MO45, 1335 East Catherine St., Ann Arbor, Mich. 48109.

The properties examined included growth kinetics, adhesiveness (as determined by resistance to trypsin-mediated release from plastic dishes), motility, and various hydrolytic enzyme levels. Growth kinetics were determined by adding 1×10^5 cells to dishes 35 mm in diameter in 2 ml of growth medium. At daily intervals fresh medium was added, and the cells were harvested by trypsinization and enumerated with the use of an electronic particle counter (model ZB; Coulter Electronics, Garden Grove, Calif.).

For the determination of adhesiveness, 1×10^5 cells were added to the 35-mm dishes and allowed to grow for 18 hours. The dishes were then washed twice with phosphate-buffered saline and treated with a solution of 0.25% trypsin (1:250; Difco Laboratories, Detroit, Mich.). The plates were rotated at 50 r/min at room temperature, and samples of the supernatant were taken at 1-minute intervals. After 10 minutes, all cells that were still attached were removed by vigorous trituration. Cells were enumerated with an electronic particle counter, and the percentage of cells detached at each time period was determined. The procedure has been described in detail in a recent report (*13*).

We determined cell motility with the use of an agarose assay as described previously (*16*). A single-cell suspension was prepared and centrifuged into a pellet. The pellet was resuspended in growth medium containing 0.2% Seaplaque agarose (Marine Colloids, Inc., Rockland, Maine). Drops of 5-μl size containing about 1×10^5 cells were added to wells of a microtiter plate. After the drops had solidified, they were overlayered with growth medium. The plates were then incubated at 37°C for 18 hours. Cell migration was determined at this time by measuring the distance between the edge of the agarose drop and the leading edge of the migrating cells.

We measured hydrolytic enzyme activities, i.e., nonspecific protease activity, β-glucosaminidase activity, and chymotrypsin-like esterase activity. Hemoglobin hydrolysis was used as a measure of nonspecific protease activity. It was measured by a highly sensitive solid-phase assay as described in a previous report (*17*). The substrate was dried onto the surface of microtiter wells at 10 μg/well. Viable tumor cells, 5×10^6/well, were added in a 200-μl volume, and the assay was run for 1 hour at 37°C. Trypsin (type I, twice crystallized from bovine pancreas; Sigma Chemical Co., St. Louis, Mo.) was used as a control enzyme.

Glucosaminidase activity was measured with the use of a standard colorimetric assay (*18*) with *p*-nitrophenyl-*N*-acetyl-D-glucosaminide as the substrate. For this assay and the chymotrypsin-like esterase assay, we prepared cell extracts by homogenization and three cycles of freeze-thawing in 0.1% Triton X-100 detergent. The extracts were diluted to contain 1 mg protein/ml. Cell extract protein (50 μg) was incubated with the substrate for 30 minutes at 37°C. Jack Bean β-*N*-acetylglucosaminidase (Sigma Chemical Co., St. Louis, Mo.) was routinely used as control enzyme for these studies.

The substrate *N*-acetyl-DL-phenylalanine-β-naphthyl ester was used as the substrate for the chymotrypsin-like esterase activity (*19*). This substrate is susceptible to chymotrypsin-like enzymes and is also hydrolyzed by a number of nonproteolytic esterases. Extract protein (100 μg) was incubated at 37°C for 45 minutes with the substrate. Chymotrypsin (type II, crystallized three times from bovine pancreas) was used as control. With each of the three enzyme assays, the linear portion of the curve was determined with respect to enzyme concentration at a given point in time and with respect to time at a given enzyme concentration. Concentrations of the viable tumor cells or tumor cell extracts were chosen to fit within the linear portion of the curve. The substrates and control enzyme preparations used in these assays were obtained from Sigma Chemical Co.

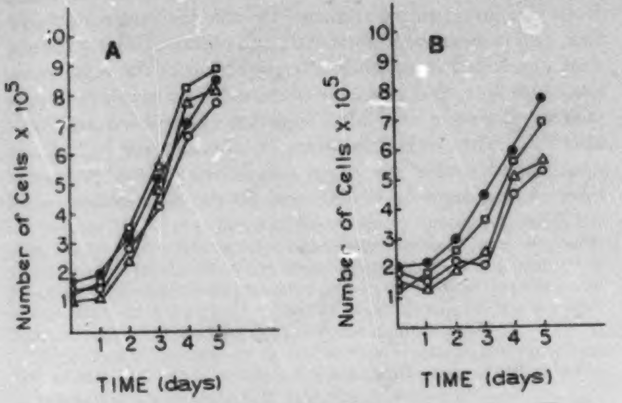
In addition to examination of these in vitro characteristics, in vivo behavior of the cell lines was characterized at periodic intervals. This involved determining the transplantability or the percentage of syngeneic mice that developed primary tumors after injection of 1×10^5 cells in the right hind footpad, and the metastatic potential or the percentage of injected animals that developed metastatic tumors in the lungs and the number of lung tumors per animal. We used 4- to 6-week-old, inbred female C57BL/6 mice in these experiments. The high- and low-transplantable lines at a given passage level were compared to one another on the same day. Animals chosen at random from the common stock were used with both groups. Thus, although different batches of animals were used to compare the groups from passage to passage, animals from the same batch were used with both prototype lines at a given passage.

RESULTS

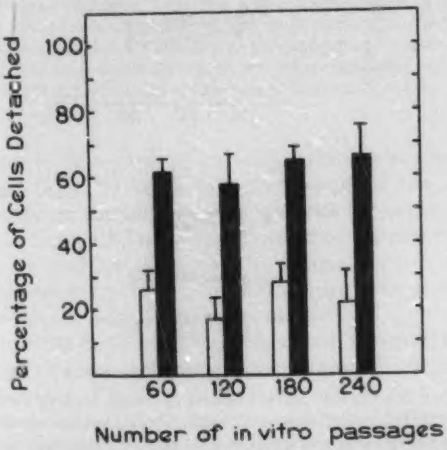
Stability of the Prototype Lines

The two prototype lines exhibited several biologic differences when they were initially isolated and tested as described in our recent reports (*6, 7, 13–15, 20*). There were differences in adhesiveness, motility, and levels of several hydrolytic enzyme activities. There were also differences between these lines in ability to induce tumors when transplanted into syngeneic mice and in the tumors' ability to spontaneously metastasize.

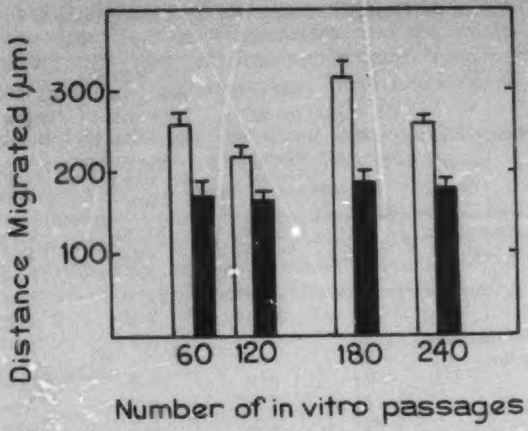
The same characteristics that were initially examined in the two prototype lines were followed over a 2-year period during which time both cell populations were maintained under standard conditions (as defined in "Materials and Methods"). The results of the various in vitro assays performed as shown in text-figures 1–4. Growth curves shown in text-figure 1 indicate little variation in the high-transplantable line over the period of observation. Similarly, the growth rate of the low-transplantable line showed little variation over the same period, although the saturation density was somewhat higher in the later passages. Adhesiveness, as indicated by sensitivity to trypsin-mediated release from the surfaces of plastic culture dishes, and motility are shown in text-figures 2 and 3. Both characteristics were stable in the two lines over the 2-year observation period. The high-transplantable cells were always more adhesive and more motile than the low-transplantable cells. Enzyme activities are shown in text-figure 4. We previously reported (*6, 7*) that the high-transplantable cells had higher levels of glucosaminidase activity than the low-transplantable cells. However, after several passages under standard conditions, the levels of glucosaminidase activity in the high-transplantable cells fell and the levels in the low-transplantable cells rose. Activities in both cell lines reached similar levels by passage 20 and have remained relatively stable ever since. Although protease activity was not routinely measured during the initial phase of this study, when this activity was measured starting at passage 30, there was no significant difference between the lines and no evidence of modulation with time in culture with either line. In contrast, the *N*-acetyl-DL-phenylalanine-β-naphthyl esterase activity was greater in the low-transplantable cells than in the high-transplantable cells at the time of isolation and remained so throughout the observation period. There was no evidence of modulation of the activity in either line.



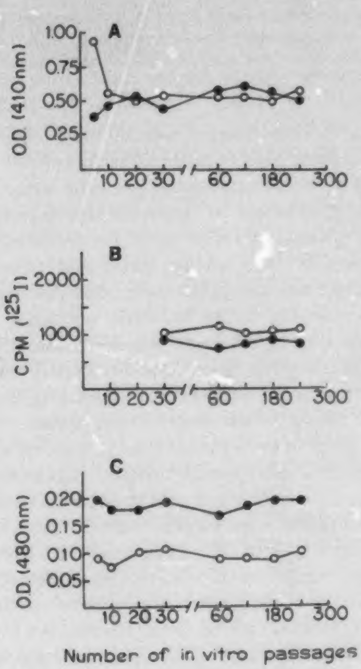
TEXT-FIGURE 1—In vitro growth rates of the prototype lines. SE were <10% of the mean values. A) High-transplantable line. B) Low-transplantable line. O—O, passage 60; Δ—Δ, passage 120; □—□, passage 180; ●—●, passage 240.



TEXT-FIGURE 2—Trypsin-mediated detachment of the prototype lines. Cells were plated at 1×10^5 cells/ml in 35-mm culture dishes at time 0 and assayed for sensitivity to trypsin-mediated detachment 18 hr later (*13*). The assay involves sampling at 2-min intervals over 10 min, although only 1 time point (at 5 min) is shown. Values are means ± SEM of the percentage of released cells from triplicate plates. The *t*-test was used to evaluate the significance of the difference between the high- and low-transplantable lines at each passage. $P\leq 0.05$ for the differences. □, High-transplantable line; ■, low-transplantable line.



TEXT-FIGURE 3.—Motility of the prototype lines was assayed with the use of the agarose procedure (*16*). □, High-transplantable line; ■, low-transplantable line. Values are the average distances ± SEM from the leading edge to the edge of the agarose drop on 4 sides of each of 4 drops. Significance of the difference between the high- and low-transplantable lines at each passage was evaluated by Student's *t*-test. $P<0.001$ for all the differences.



TEXT-FIGURE 4.—Enzyme activity assays of the prototype lines were done as described in "Materials and Methods" and in previous publications (*17–19*). A) Glucosaminidase activity. B) Protease activity. C) Chymotrypsin-like esterase activity. O—O, High-transplantable line; ●—●, low-transplantable line. The glucosaminidase and chymotrypsin-like esterase values are averages of triplicate samples. SE were <10% of the means. Protease values are averages of 4 samples; standard errors were <15% of the means. Student's *t*-test was used to evaluate the significance of the differences between the high- and low-transplantable lines at each passage. The differences in the chymotrypsin-like esterase activity were significant at all passages ($P\leq0.05$). The other enzyme activities were not significantly different between the two prototype lines. O. D.=optical density.

TABLE 1.—*Transplantability and metastasis formation by the prototype lines*

Cell population	No. of in vitro passages	No. of tumors/No. of mice given injections[a, b]	No. of mice with pulmonary metastases/No. of mice with primary tumors[b, c]	No. of metastases/mouse, mean ± SEM[b, c]
High-transplantable line	10	30/30	11/30	2±1
	30	20/20	4/20	5±3
	60	8/8[d]	2/8	5±4
	120	18/20	11/18	6±4
	240	20/20	7/20	4±3
Low-transplantable line	10	2/10	0/2	None
	30	—	—	—
	60	5/30	0/5	None
	120	7/25[d]	0/7	None
	240	5/20	0/5	None

[a] Each animal received 1×10^5 viable tumor cells in the right hind footpad. All animals were examined at 3- to 5-day intervals and were scored as negative if there was no evidence of tumor growth 35 days after injection (*6*).

[b] —=not measured.

[c] Animals were killed with ether after 35 days, and their lungs were examined for metastatic tumor nodules after inflation with india ink (*21*).

[d] Significance levels were determined by a chi-square test. When the passage 60 high-transplantable line was compared with the passage 120 low-transplantable line (the 2 groups with the smallest difference), the *P*-value was <0.01.

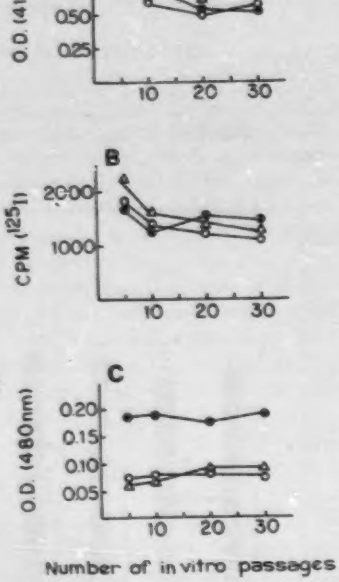
In addition to measuring these in vitro characteristics, both cell lines were also compared with regard to various parameters of in vivo behavior at periodic intervals. Table 1 shows the percentage of animals developing primary tumors after injection of 1×10^5 cells. It can be seen that the high-transplantable cells always produced tumors in virtually 100% of the animals given injections. Ability to induce tumors was somewhat more variable with the low-transplantable cells, but in all cases a substantially lower percentage of animals given injections developed tumors. Furthermore, there was no evidence of increasing transplantability over the course of the observation period.

In addition to producing tumors at a high rate, the high-transplantable cells also spontaneously metastasized from the primary tumors to the lungs of the tumor-bearing mice. The rate of spontaneous metastasis varied from a low of 20% at passage 30, to a high of 61% at passage 120. Overall, lung metastases were identified in 35 of the 96 animals (36%) that developed primary tumors after injection of the high-transplantable cells. In contrast to these results, no lung metastases were identified in any of the animals that developed primary tumors after injection of the low-transplantable cells (table 1).

On two separate occasions, stock cultures of each line that had been frozen during the initial phase of the study were removed from the freezer and established in culture. They were then injected into syngeneic mice (1×10^5 cells in the right rear footpad) and compared to the lines maintained continually in culture. The prototype lines had been in culture for periods of approximately 1 and 1.5 years at the time when the comparisons were made. The lines reestablished from frozen stocks maintained their distinctive features with regard to in vivo behavior. On both occasions the high-transplantable line formed tumors in 100% of the animals given injections and spontaneously metastasized in 35–50% of the tumor-bearing animals. The low-transplantable line, however, only formed tumors in 4 out of 16 animals on the first occasion and in 2 out of 20 animals on the second. No evidence of metastases was observed in any of the 6 tumor-bearing animals or in the 30 non-tumor-bearing animals.

Stability of Isolates Derived From the High- and Low-Transplantable Line-Induced Tumors

To further assess the stability of these cell lines, we established tumors in C57BL/6 mice and subsequently reestablished them in culture. Two isolates were obtained from primary tumors induced by the high-transplantable line, two isolates were obtained from metastatic lung tumors that developed in animals after injection of the high-transplantable line, and two were obtained from primary tumors that developed in mice after injection of the low-transplantable line. After reestablishment in culture, each isolate was maintained under the same conditions as the prototype lines. At passages 5, 10, 20, and 30 the new isolates were



TEXT-FIGURE 5.—Enzyme activity assays of tumor isolates were done as described in previous reports (*17–19*). ○—○, Isolates obtained from primary tumors that developed in animals given injections of the high-transplantable line; △—△, isolates obtained from metastatic lung tumors that developed in animals given injections of the high-transplantable line; ●—●, isolates obtained from primary tumors that developed in animals given injections of the low-transplantable line. SE were routinely <10% of the mean values in all three procedures. Differences between the isolates derived from tumors induced by the high-transplantable line and isolates derived from the low-transplantable line in chymotrypsin-like esterase activity were calculated by the Student's *t*-test and were found to be significant $P \leq 0.05$ O. D.=optical density.

TABLE 2.—*Transplantability and metastasis formation by six tumor isolates*

Tumor isolate[a]	No. of in vitro passages	No. of tumors/No. of mice given injections[b]	No. of mice with pulmonary metastases/No. of mice with primary tumors[c]	No. of metastases/mouse, mean±SEM[c]
1	5	10/10	4/10	2±1
	10	20/20	7/20	4±1
	20	20/20	5/20	1±1
2	5	8/8[d]	5/8	2±2
	10	20/20	8/20	2±1
	20	20/20	6/20	2±2
3	5	20/20	9/20	5±1
	10	19/20	8/19	4±3
	20	20/20	8/20	4±3
4	5	20/20	15/20	7±2
	10	20/20	4/20	5±1
	20	20/20	9/20	5±1
5	5	9/20[d]	1/9	None
	10	5/20[d]	0/5	None
	20	4/20[d]	0/4	None
6	5	2/6[d]	0/2	None
	10	8/20	0/8	None
	20	4/20	0/5	None

[a] Isolates 1 and 2 were obtained from primary tumors induced by the high-transplantable line. Isolates 3 and 4 were obtained from metastatic tumors which developed in the lungs of animals that had been given injections of the high-transplantable cells in the footpad. Isolates 5 and 6 were obtained from primary tumors which developed in mice after injection with the low-transplantable cells in the footpad.

[b] Each mouse received 1×10^5 viable tumor cells in the right hind footpad at 3- to 5-day intervals and was scored as negative if there was no evidence of tumor growth 35 days after injection (*6*).

[c] Mice were killed with ether after 35 days, and their lungs were examined for metastatic tumor nodules after inflation with india ink (*21*).

[d] Significance levels were determined by a chi-square test. Each of the values obtained with the low-transplantable isolates was compared with the value obtained with the high-transplantable isolate 2 at passage 5. Since fewer animals were used in this group than in the other groups, values that are statistically significant when compared to this group will also be statistically significant when compared to the other groups. $P \leq 0.05$ for all values obtained with isolates 5 and 6.

examined with regard to the same characteristics as the prototype lines. In summary, by passage 5 the in vitro growth rates of the isolates were very similar to those of the prototype lines. Likewise, there was no difference in adhesiveness or motility between the tumor isolates and the respective prototype lines. Similar results were obtained at passages 10, 20, and 30 (data not shown).

Remarkable differences were observed, however, between the tumor isolates and the prototype lines with regard to enzyme levels. The tumor isolates had higher levels of protease and glycosidase activities at passage 5 than did the prototype lines. The chymotrypsin-like esterase activity was slightly elevated in the isolates. Of those isolates derived from the high-transplantable line, the metastatic tumor isolates had higher levels of activity than did the primary tumor isolates. By passage 10 the differences between the various isolates and the parent lines were reduced, and by passage 20 and subsequent passages the differences were gone. From that point on, all isolates and both prototype lines had similar levels of protease and glycosidase activities; the low-transplantable prototype line and the isolates derived from that line still had much higher levels of the chymotrypsin-like esterase activity. These data are shown in text-figure 5.

The six isolates were also tested with regard to in vivo behavior at passages 5, 10, and 20. The overall data obtained at passage 5 show a slight trend toward increasing transplantability in the recent isolates. However, even this slight trend disappeared by the later passages. Thus with regard to in vivo behavior the isolates resembled the prototype lines from which they were derived. The in vivo data are shown in table 2.

DISCUSSION

This report addresses the problem of tumor line stability: Are the numerous subpopulations of tumor cells that can be isolated from uncloned tumors stable or are they continually undergoing phenotypic alteration? This question is important for at least two reasons. First, many heterogeneous tumor models are being used in efforts to determine what particular phenotypic characteristics contribute to cancer (*5–7, 13–15, 20, 22–25*), and the results of such studies would not be valid if the populations used were in a continual state of change. Second, it has been suggested that variant tumor populations arise early in the course of tumor development and that it is specific subpopulations that give rise to metastases (*2, 3*). The ability to prove or disprove such a theory requires the existence of clones of metastatic and nonmetastatic cells stable enough to be examined after isolation.

The results presented in this report show that in at least one model system a number of phenotypic characteristics are stable in tumor cell lines maintained continually in culture for a long period of time (≤2 yr) or passed through syngeneic animals and reestablished in culture. In terms of in vitro growth rates, adhesiveness, motility, and chymotrypsin-like esterase activity, there was no evidence of modulation in either of the prototype lines examined. Furthermore, there was no evidence of modulation in the degree of transplantability or in the frequency of spontaneous metastasis formation with either line. It should be noted that since metastasis formation is to a large extent a function of primary tumor transplantability and growth kinetics, the lack of change in the rates of metastasis formation probably reflects the lack of change in transplantability.

These results show that at least with regard to the properties examined here, the populations generated from the parent tumor are not undergoing constant phenotypic drift simply as a result of in vitro or in vivo maintenance. Furthermore, they add strength to our previous findings of a strong correlation between adhesiveness and transplantability and the lack of correlation between in vitro growth rates and transplantability (*6, 7, 13–15*).

In contrast to these results, the protease and glycosidase activities did show evidence of modulation. When the conditions under which the cells were maintained were altered [i.e., going from medium with human serum to medium with FCS (*6*) and going from culture to primary tumors to metastatic tumors to culture (*7*)], the enzyme activities varied. Since the activities could be manipulated in a predictable way depending on the conditions of maintenance, this suggests that environmental pressures induced the expression of different levels of enzyme activity in a given cell population. Alternatively, it is possible that the environmental pressures selected for preexisting subpopulations that had arisen during the course of tumor growth. With the presently available data it is impossible to definitively choose between these two explanations. Whatever the reason for the modulation of these enzyme activities, once the cells were adapted to culture and maintained under standard conditions, the enzyme activities were as stable as the other properties that were examined.

It is difficult to know how general the findings are that were made with this fibrosarcoma model until similar studies are done with cell lines derived from a number of other tumors. To date not enough systems have been investigated thoroughly, probably because of the time involved in such studies. In a model that has been observed over a period of years, Sanford et al. (*26, 27*) identified stable differences in anaerobic energy metabolism in variants derived from transformed mouse fibroblasts; the differences were associated with stable differences in transplantability. A recent study by Chambers et al. (*28*) also suggested that tumor cell lines could remain stable for a prolonged period of time in vitro. Their study, however, spanned only a 3- to 4-month period, and it is not known whether these lines will demonstrate the same properties after they are maintained for a longer period of time.

In summary, these results do not suggest that tumor progression does not occur; it clearly does occur (*29*). Furthermore, these results do not conflict with the recent evidence presented by Poste, Doll, and Fidler (*30*) who showed that while individual clones that form an established tumor line may be unstable, the overall population comprised of these clones is very stable.

Development of Resistance to MOPC-315 Plasmacytoma After Intralesional and Intraperitoneal Melphalan Therapy of Tumor-Bearing BALB/c Mice. I. Enhancement of In Vivo Rejection Responses by Combined Chemotherapy–Immunotherapy[1,2]

Aliza Adler, *Ph.D.*,[3,4] *and* **Irit Altbaum**, *M.Sc.*[5,6]

ABSTRACT—Experimental and clinical evidence indicates that some chemotherapeutic agents may enhance tumor cell immunogenicity. This study was undertaken to test the possibility that melphalan [L-phenylalanine mustard (L-PAM)]—a clinically useful drug—can modulate tumor cells in vivo and in vitro in a syngeneic experimental system of MOPC-315 plasmacytoma in BALB/c mice and that this modulation can be expressed in vivo by enhanced tumor resistance. Tumor-bearing mice were treated with L-PAM intralesionally and ip by a split-course chemotherapy to avoid excessive toxicity of the drug. As a result of this treatment, about 60% of the mice had complete tumor regression; of these, 40–60% were resistant to viable tumor cell challenge and were designated as "cured-immune." Immunogenicity of irradiated MOPC-315 was tested in BALB/c mice; significant protection against tumor cell challenge was not achieved. In vitro L-PAM-treated MOPC-315 cells induced a measurable but weak antitumor response. Combination of both therapeutic approaches, i.e., chemotherapy and active immunization by L-PAM-treated tumor cells, was attempted with the use of various schedules. Immunotherapy given after L-PAM-induced tumor regression significantly enhanced in vivo antitumor response to challenge by 10^4 and 10^5 viable MOPC-315 tumor cells. When immunotherapy was attempted before chemotherapy in the presence of actively growing though still occult tumor, it reduced the chemotherapy cure rate and resulted in a low rate of tumor resistance. Addition of BCG did not remarkably affect the results. The findings point to the importance of timing of active immunization relative to tumor load and chemotherapy. The implication is that chemotherapy-induced regression is mediated by host immune mechanisms in this experimental model.—JNCI 1982; 68:963–969.

Experimental evidence indicates that host antitumor mechanisms are activated under conditions of tumor regression caused by chemotherapeutic agents. Development of resistance to viable tumor cell challenge was demonstrated in several experimental models, e.g., in mice bearing plasmacytomas after cure by aniline mustard (*1–4*) or by cyclophosphamide (*5, 6*) and in guinea pigs with hepatomas after intralesional adriamycin (*7*), L-PAM, or 1,3-bis(2-chloroethyl)-1-nitrosourea (*8*).

Of the various treatment modalities employed in clinical and experimental cancers, chemotherapy and immunotherapy are directed toward control of systemic disease and, theoretically, should complement each other. Although chemotherapy frequently partially controls the disease by significantly reducing the tumor burden, it rarely affects cure, whereas immunotherapy at its best was shown only to affect minimal residual disease (*9, 10*). A combination of the two modalities should entail the possibility of an additive effect of the enhancement of tumor cell immunogenicity by chemotherapy and the stimulation of relevant host antitumor response by immunotherapy.

An investigation of chemical modulation of tumor cells with respect to their expression of tumor-associated antigens was reported (*11*); also investigated were alkylating agents (*12*), some of which are employed in clinical chemotherapy (*13–16*).

It was suggested that the mechanism of action of chemotherapeutic agents on tumor cells both in vivo and in vitro is either that the agent directly modulates the tumor cell (*12, 14*) or the drug acts indirectly as a hapten and forms a tumor-associated protein–hapten conjugate, thus enhancing the immunogenicity of the carrier protein (*15, 16*).

The selection of L-PAM for this investigation was based on the following considerations: *1*) L-PAM has haptenic activity and can induce a specific antitumor response after active immunization by the tumor–protein–L-PAM conjugate (*16, 17*); *2*) the direct action of L-PAM on tumor cells permits effective intratumoral therapy, which ensures maximal contact between the drug and tumor cells in vivo; *3*) indirect evidence indicates that such in vivo contact may have a late systemic antitumor effect in human melanoma, for regional perfusion with L-PAM resulted in some instances in disappearance of distant lesions (*18*); *4*) L-PAM is widely employed in clinical cancer therapy for multiple myeloma, melanoma, breast cancer, ovarian cancer, and other cancers.

We found the experimental model of the mouse plasma-

cytoma suitable for this study because of its responsiveness to L-PAM therapy both by intralesional and systemic administrations and because of the indication that tumor regression caused by this treatment is accompanied by development of in vivo tumor resistance (*19*).

One of the main objectives of this investigation was to establish optimal sequences and schedules for combined chemotherapy–immunotherapy to achieve the highest cure rate and to induce strong tumor resistance. This first part of the study deals with development of methods for in vivo chemotherapy and active immunization by in vitro L-PAM-treated tumor cells and with the combination of the two methods. The ultimate goal of this ongoing work is to identify the immune mechanisms involved in tumor rejection after L-PAM therapy and to apply the knowledge gained for selective stimulation of such responses.

MATERIALS AND METHODS

Animals.—Male inbred BALB/c mice, 6–8 weeks old and weighing approximately 20 g, were obtained from The Weizmann Institute, Rehovot, Israel, and used throughout this study.

Tumor cells.—Mineral oil-induced MOPC-315 plasmacytoma, originally developed by Potter and Walters (*3*), was obtained from Dr. D. Givol, The Weizmann Institute, and maintained in vivo by serial sc inoculation into syngeneic BALB/c mice. The cells were irradiated by tele-cobalt at 3,000 and 6,000 rad.

L-PAM.—L-PAM was obtained as dry powder from Wellcome Foundation Ltd., London, England. It was diluted in an acid-alcohol solution and in a diluent supplied by Wellcome. We used 0.2 ml of L-PAM in an appropriate concentration for intratumoral or ip injection in tumor-bearing mice.

In vitro L-PAM treatment of tumor cells was performed as follows: A single cell suspension of 10^6 tumor cells in 2.5 ml PBS containing 25 μg of L-PAM was incubated in a shaker bath for 30 minutes at 37°C in 50-ml plastic tubes. The tumor cells were then washed twice in 50 ml PBS and tested for viability by trypan blue before immunization.

Immunization.—Immunization was performed with single cell suspensions obtained from in vivo grown ascites MOPC-315 tumor. This preparation had a high viability count compared to the approximately 50% viability of the suspension prepared from the subcutaneous tumor nodule (table 1). Immunization was done by sc injection of irradiated or L-PAM-treated cells, given twice at weekly intervals. Unless otherwise specified, 10^6 MOPC-315 cells were used as the immunizing inoculum.

BCG.—The (freeze-dried) BCG vaccine used for admixture with tumor cells for sc immunization as well as for intratumoral injection was from Glaxo Laboratories (Greenford, Middlesex, England) and contained approximately 10^6 viable organisms/0.1 ml.

Viable tumor cell challenge.—After the LD_{50} of tumor cells was established (10^2 tumor cells in repeated experiments), a dose of 10^4 viable tumor cells was chosen for challenge inasmuch as this dose gave a reproducible 100% tumor take. Thus a tumor cell challenge of 10^4 cells was used in most experiments, unless otherwise specified.

RESULTS

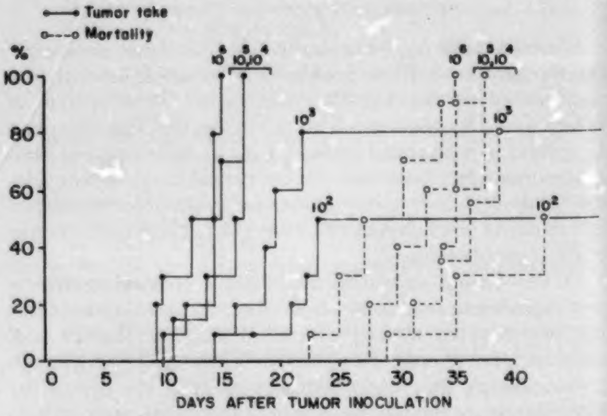
Tumor Take and Mortality

To establish the biologic behavior of MOPC-315 plasmacytoma in BALB/c mice in terms of tumor take and subsequent mortality, we titrated the tumor cells obtained from in vivo passage by sc injection of various tumor cell concentrations. The results of three such experiments are presented in text-figure 1, where 8 mice were used for each tumor cell concentration in each experiment. Palpable nodules (0.5–0.8 mm in diameter) became manifest in some mice at 10–16 days. Subsequently, all mice showed tumor takes and died within 30–35 days when tumors as large as 2.5–3 cm were present. No spontaneous tumor regressions were observed. The LD_{50} fell between 10 and 10^2 tumor cells, and a 10^4-cell dose showed 100% take in all experiments as calculated from curves shown in text-figure 1.

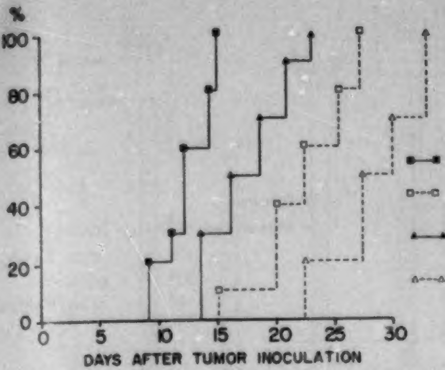
Effect of BCG on Tumor Take and Mortality

We tested the possible effect of BCG on tumor take and on mortality of BALB/c mice inoculated with MOPC-315. Three schedules of BCG administration were tested: *1*) systemic pretreatment of mice by subcutaneous BCG on day 14 before tumor inoculation; *2*) admixture of BCG with viable tumor cells before inoculation; and *3*) intratumoral BCG injection. The results of experiments with the use of schedules *1* and *2* are shown in text-figures 2 and 3.

There were some delays in tumor take and prolongation of survival but no tumor regressions or cures were seen in mice given injections of BCG before tumor inoculation and those given injections of the BCG–tumor cell mixture, as compared to non-BCG-treated tumor-inoculated mice. Direct intratumoral BCG injection of small, medium-sized, or large tumors had no effect on further tumor progression or survival. No tumor regressions were observed after intratumoral BCG injection (results not shown). We concluded that the MOPC-315 tumor is only weakly responsive to BCG-mediated antitumor effector mechanisms.



TEXT-FIGURE 1.—Tumor take and mortality of BALB/c mice after sc injection of MOPC-315 in various concentrations. Pooled data of three consecutive experiments are shown; 24 mice were used for each cell concentration.



TEXT-FIGURE 2.—Tumor take and mortality of BALB/c mice after sc injection of 10^4 tumor cells in normal (control) mice and in mice pretreated on day 14 with sc BCG (10^8 viable organisms/mouse). Pooled data of three experiments are shown; 18 mice were in each group.

Immunogenicity of MOPC-315 Tumor Cells

The accepted procedure for testing the immunogenicity of a given tumor in a syngeneic system is to either excise the local tumor or actively immunize animals with irradiated tumor cells (alone or admixed with BCG) and to look for protection against viable tumor cell challenge in surgically cured or preimmunized animals. Both approaches were tried in the MOPC-315 plasmacytoma in BALB/c mice with negative results. The subcutaneous tumor nodule, even if excised early (at a diameter of 0.5–0.8-mm), regrew at the site of surgery and the tumor took at distant sites upon viable tumor cell challenge. Thus surgical cure was not achieved.

Active immunization by means of irradiated tumor cells (treated with 3,000 and 6,000 rad) given alone or admixed with BCG was attempted by the sc route on days 1 and 7 followed on day 21 by viable tumor cell challenge. No protection against challenge with 10^4 viable tumor cells was achieved (text-fig. 4). When immunized mice were challenged with 10^3 tumor cells, tumor take was similar to that in nonimmunized mice (results not shown).

These studies indicate that the MOPC-315 plasmacytoma is a nonimmunogenic or weakly immunogenic tumor and that different approaches are needed to elicit tumor rejection.

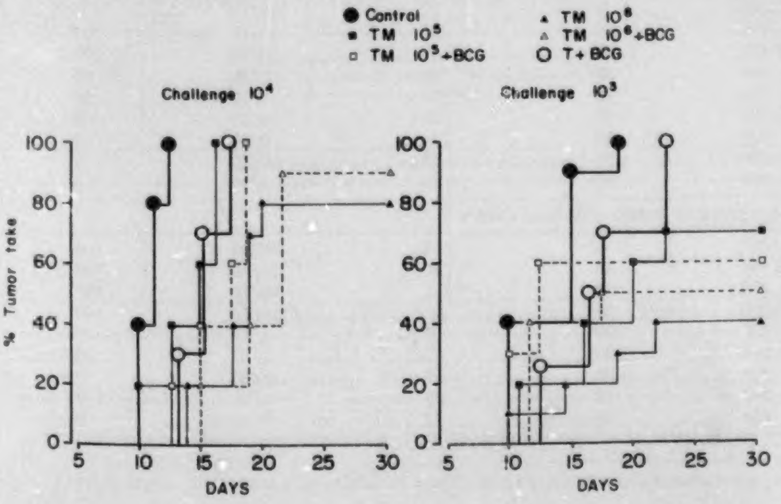
Active Immunization by In Vitro L-PAM-Treated MOPC-315 Cells

We performed a pilot experiment to establish the optimal conditions for in vitro treatment of tumor cells by L-PAM. Viable tumor cells were exposed to decreasing concentrations of L-PAM from 1,000 to 1 μg L-PAM/10^6 tumor cells for 30 minutes at 37°C. The effect of these drug concentrations on [^{3}H]dThd uptake, trypan blue staining, and tumorigenicity of treated MOPC-315 cells was examined. Results of two experiments are presented in table 1.

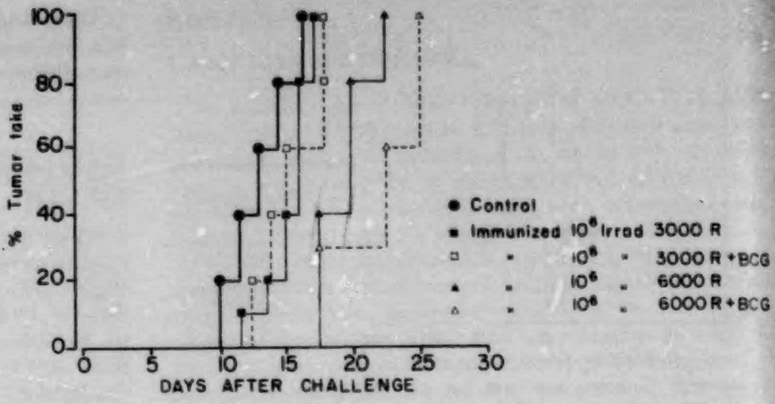
The lowest L-PAM concentration that completely abolished tumorigenicity was 25 μg/10^6 tumor cells, while cells treated with 5 μg L-PAM gave 40 to 60% tumor take, and those treated with 1 μg showed 100% take. No correlation was found between tumor take by L-PAM-treated cells and reduction in [^{3}H]dThd incorporation; [^{3}H]dThd was reduced at a similar rate at all L-PAM concentrations except 1 μg. Thus [^{3}H]dThd incorporation cannot serve as a sensitive index of tumorigenicity.

Vital staining by trypan blue was tested as an indicator of membrane damage and not of tumorigenicity. Concentrations of 100 μg L-PAM/10^6 tumor cells and above significantly reduced trypan blue-negative cells, whereas lower concentrations did not affect cell viability. Therefore, all experiments of active immunization were performed with tumor cells treated with 25 μg L-PAM, a concentration answering the criteria of minimal cell membrane damage, yet rendering the cell nontumorigenic.

The diluent used for the L-PAM concentration of 1,000 μg completely abolished [^{3}H]dThd uptake and reduced cell viability by trypan blue criterion, whereas the tumorigenicity of MOPC-315 cells was unaffected (100% take), even showing enhanced tumor growth. This finding indicates that while the diluent may cause transient cell damage with



TEXT-FIGURE 3.—Tumor take in BALB/c mice preimmunized by in vitro L-PAM-treated tumor cells (TM) upon challenge of 10^4 and 10^3 viable MOPC-315 cells. Immunization was done by 10^5 and 10^6 cells (TM) with or without admixture of BCG. Control mice were inoculated with viable 10^4 and 10^3 MOPC-315 cells (T) alone (●——●) or admixed with BCG (○——○). Pooled data of two experiments are shown, 20 mice were in each group.



TEXT-FIGURE 4.—Tumor cell challenge in mice preimmunized with 10^6 MOPC-315 tumor cells irradiated with 3,000 and 6,000 rad (R) with or without admixture of BCG on days 1 and 7. Challenge dose of 10^4 MOPC-315 cells was given on day 21.

in vivo tumor cell recovery, treatment with L-PAM causes irreversible cell death.

We performed active immunization by sc injection of 10^5 and 10^6 L-PAM-treated cells on days 1 and 7 followed on day 21 by viable tumor cell challenge. This experiment was repeated twice, with and without admixture of BCG, with 20 mice in each treatment group (text-fig. 3). Minimal protection by immunization could be detected when mice were challenged with 10^4 viable cells. With a lower dose of 10^3 viable cells, a significant proportion of animals showed tumor resistance. When survivors of the 10^3-cell challenge were rechallenged with 10^4 viable cells, all were found to be resistant. Thus challenging preimmunized animals with a low dose of viable tumor cells has a boosting effect on in vivo tumor resistance. The immunizing dose of 10^6 L-PAM-treated MOPC-315 cells resulted in a rate of protection higher than that of the 10^5 cell dose. While some tumor protection was achieved by active immunization with L-PAM-treated cells, this schedule of immunization shows low efficacy in the MOPC-315 plasmacytoma in BALB/c mice. Addition of BCG to the tumor cell vaccine did not enhance tumor resistance.

Intratumoral and Systemic Therapy of Established Tumors With L-PAM

A pilot study showed that tumoricidal doses of L-PAM are toxic to BALB/c mice. For active tumor regression, intralesional or ip doses of 500–600 μg L-PAM/mouse are needed (25–30 mg/kg body wt). These doses caused 40–50% mortality of mice due to toxicity. Since lower doses of L-PAM did not cause complete tumor regression, a split-course

Text-figure 5.—Percentages of L-PAM-cured and "cured-immune" mice (resistant to 10^4 tumor cell challenge). Various schedules of chemotherapy are presented for medium-sized (M) and large (L) tumors: Split-course of L-PAM was given intratumorally (i.t.), ip (i.p.), and in combination; mice in the T-group were inoculated with tumor on day 7 but remained clinically tumor-free. ——=range of results from several experiments for percentage of cure; -----=percent of antitumor response. *Numbers in parentheses* represent total numbers of mice pooled from several experiments for each schedule.

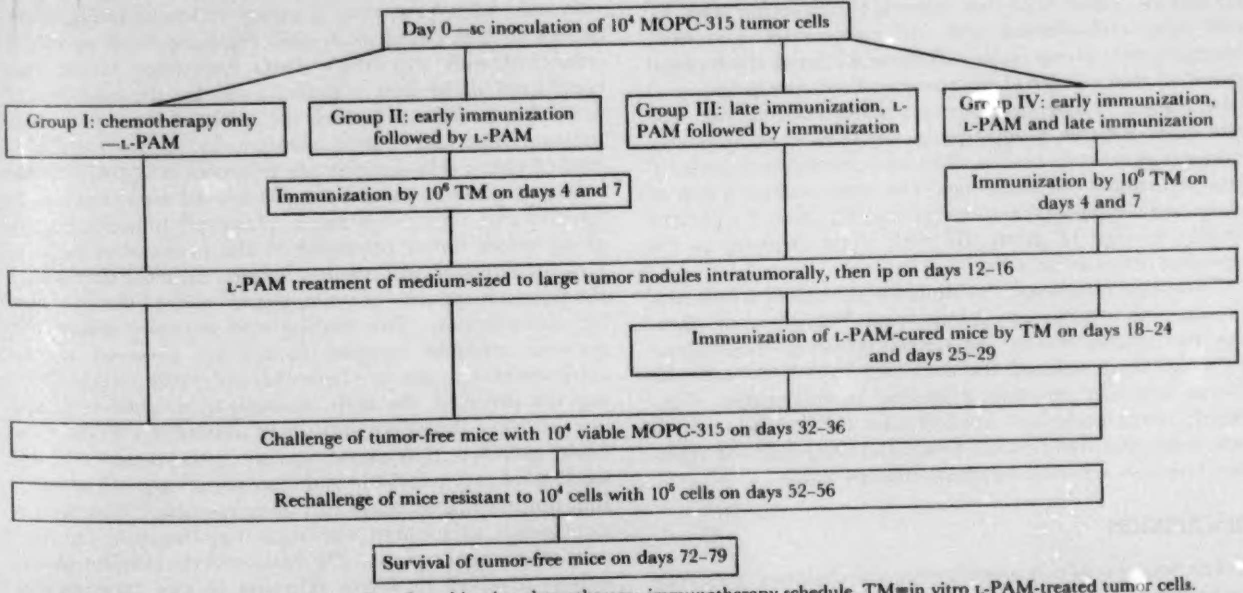
therapy was devised: Tumor-bearing mice were treated with 200–300 μg (10–15 mg/kg body wt) L-PAM on day 1; after 2–3 days they were treated with higher doses of 400–500 μg (20–25 mg/kg body wt). This schedule reduced mortality due to toxicity and achieved a high proportion of tumor regressions.

We experimented with various routes of L-PAM administration (text-fig. 5). In all six experiments L-PAM treatment resulted in complete tumor regression in 43–64% of mice and in partial regression or no effect in the remaining 36–57% of mice. Repeated L-PAM administration did not significantly improve the cure rate achieved by one split-course chemotherapy, which indicates tumor cell resistance to chemotherapy in a certain proportion of animals. Increased toxicity was observed after repeated L-PAM treatments.

Rapid development of subcutaneous tumor nodules from small (0.5 cm) to medium-sized (0.5–0.9 cm) and large (1–1.5 cm) nodules precludes accumulation of sizable groups of animals carrying small tumors. Therefore, most experiments were performed with medium-sized and large tumors.

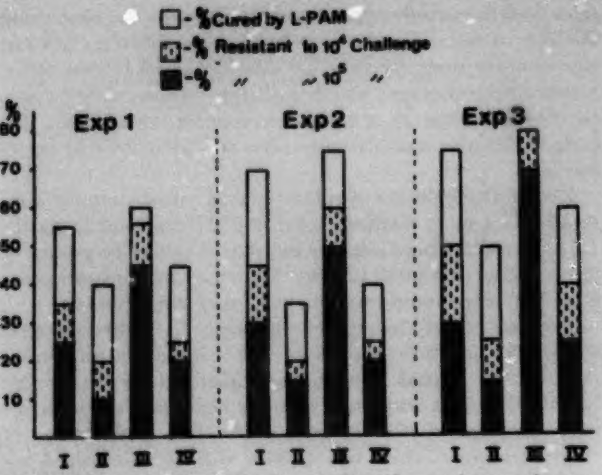
The rate of cure (complete regression) by different routes of L-PAM administration was quite similar in all groups (text-fig. 5). Cured mice were challenged by 10^4 viable MOPC-315 cells and those showing resistance to challenge were designated "cured-immune." The proportion of "cured-immune" mice was highest with medium-sized tumors treated with intralesional L-PAM and similar in large tumors treated with intralesional or intralesional followed by ip L-PAM. In both the medium-sized and large tumor groups L-PAM administered ip (i.p., i.p.; text-fig. 5) resulted in lower tumor resistance.

On the basis of these data most experiments were performed with mice bearing medium-sized and large tumors and were inoculated with L-PAM first intratumorally and then ip (i.t., i.p.; text-fig. 5). Mice given injections of tumor and drug treated on day 7 before tumor development (T-; text-fig. 5) with ip L-PAM (i.p., i.p.; text-fig. 5) showed low cure rates as well as low tumor resistance in cured animals. Thus prophylactic systemic chemotherapy was less effective than active chemotherapy of tumor-bearing animals in the MOPC-315 plasmacytoma system, indicating that in vivo antitumor responses are related to the size of the tumor and its biologic activity and that these may be implicated in mediating cure by chemotherapy.



Day 0—sc inoculation of 10^4 MOPC-315 tumor cells
Group I: chemotherapy only —L-PAM
Group II: early immunization followed by L-PAM
Group III: late immunization, L-PAM followed by immunization
Group IV: early immunization, L-PAM and late immunization
Immunization by 10^6 TM on days 4 and 7
Immunization by 10^6 TM on days 4 and 7
L-PAM treatment of medium-sized to large tumor nodules intratumorally, then ip on days 12–16
Immunization of L-PAM-cured mice by TM on days 18–24 and days 25–29
Challenge of tumor-free mice with 10^4 viable MOPC-315 on days 32–36
Rechallenge of mice resistant to 10^4 cells with 10^5 cells on days 52–56
Survival of tumor-free mice on days 72–79

Text-figure 6.—Schematic presentation of combination chemotherapy–immunotherapy schedule. TM=in vitro L-PAM-treated tumor cells.



TEXT-FIGURE 7.—Combined treatment by chemotherapy–immunotherapy. For group designation *see* text-fig. 6. Data of three separate experiments are shown. There were 20 mice per experiment for each treatment group.

Combined Chemotherapy–Immunotherapy

Results presented so far show that *a*) 60–70% of tumor-bearing mice can be cured by L-PAM treatment under optimal conditions with 50–60% of these mice developing tumor resistance to viable tumor cell challenge and *b*) active specific immunization of healthy mice by means of in vitro L-PAM-treated cells induces a weak but measurable rejection response. It follows that combination of the two approaches may further enhance the in vivo antitumor response.

We explored various combined chemotherapy–immunotherapy schedules. A schematic design of the experiments is presented in text-figure 6.

All 4 treatment groups were challenged with 10^4 viable tumor cells 2 weeks after the last immunization of groups III and IV. Those mice that rejected the challenge with 10^4 cells were rechallenged with 10^5 viable cells. The early immunization group (group II) showed inferior results compared to those of the chemotherapy alone group (group I) with respect to both cure rate and antitumor response. The late immunization group (group III) showed an enhanced tumor rejection response in all three experiments to both 10^4 and 10^5 tumor cell challenge. The combination group of early and late immunizations (group IV) showed a pattern similar to that of group III with slight increase in the rejection response (text-fig. 7).

These results indicate that timing of the combined chemotherapy–immunotherapy is important. When immunotherapy was applied during the actively growing tumor phase in group II, it reduced the cure rate by L-PAM and the tumor rejection response following chemotherapy. Conversely, immunotherapy applied after L-PAM-induced tumor regression significantly ($P<0.001$) enhanced the rejection response achieved by chemotherapy alone.

DISCUSSION

The first part of this investigation was designed to explore and optimize methods and treatment schedules for MOPC-315 tumor-bearing BALB/c mice. The approach was based on two main assumptions: *1*) Chemotherapy-induced tumor regression is followed by development of in vivo tumor rejection responses and *2*) these responses can be further enhanced by immunotherapy. Results of different schedules of L-PAM chemotherapy indicate that when tumor regression was achieved, cured animals had a demonstrable capacity to reject viable tumor cell challenge. While 50–70% of the mice could be cured by L-PAM, the remaining 30–50% did not respond to repeated L-PAM treatment. In this respect, the BALB/c model resembles human tumors with a certain proportion of tumor-bearing mice showing resistance to chemotherapy. Consequently, the question arises whether cure by chemotherapy is mediated by host factors such as immune mechanisms.

Irradiated MOPC-315 cells tested by active immunization of normal BALB/c mice proved to be nonimmunogenic. BCG was tested as a possible means of stimulating the antitumor responses in this experimental model without demonstrable effect. Thus enhancing the immunogenicity of MOPC-315 cells became the major issue of the investigation.

In vitro exposure of MOPC-315 cells to L-PAM was tried as a means of possible modulation of tumor cells. The technique was based on known data from the literature (*15–17*) that L-PAM can act as a hapten and thus it can enhance tumor-associated antigen recognition. Immunoprophylaxis by means of L-PAM-treated cells induced a slight in vivo antitumor response. With schedules of optimal L-PAM regimens worked out to achieve cure and an indication at hand that in vitro L-PAM-treated tumor cells can immunize mice against viable tumor cell challenge, we directed our main efforts toward the combination of the two treatment modalities to achieve the enhancement of antitumor responses.

We built the experimental design of the combined chemotherapy–immunotherapy on the assumption that intratumoral injection of L-PAM followed by systemic administration can achieve in vivo a tumor cell-modulating effect similar to that found in in vitro exposure. Such an effect, combined with the drug's direct antitumor action, was considered to be best complemented by the addition of active immunization. Indeed, the results of the experiments indicate that active immunization by in vitro L-PAM-treated tumor cells significantly enhances in vivo antitumor responses when immunotherapy is applied after chemotherapy-induced tumor regression. However, immunotherapy given before tumor regression in the presence of actively growing—though still occult—tumors, caused a decrease in the rejection capacity of animals and lowered the cure rate by chemotherapy. This finding may partially answer the question whether immune factors are involved in the achievement of cure by chemotherapy. Were immune factors not involved, the early immunization schedule would not influence the direct antitumor activity of L-PAM. One could speculate that immunization in the presence of actively growing tumors can stimulate suppressor cell activity, thus diminishing immune antitumor responses, whereas immunization after tumor regression may stimulate the relevant antitumor responses. Elucidation of the immune mechanisms involved in tumor rejection in this experimental model is the main object of ongoing investigations.

Hematopoietic Precursor Cells in Mice Treated With 4-Demethoxydaunorubicin and Doxorubicin[1,2]

Giulio Massa,[3] Giuseppe Bogliolo,[3] Francesco D'Amore,[3] Carlo Muzzulini,[3] Riccardo Ghio,[3] and Ivo Pannacciulli[3,4]

ABSTRACT—The hematologic toxicity of 4-demethoxydaunorubicin (4-dmDNR), a new anthracycline more potent and less cardiotoxic than doxorubicin (Dx), was studied. Dose-survival curves of bone marrow hematopoietic precursor cells (HPC) in situ were determined with the use of (C57BL × C3H)F_1 mice and with assays of colony-forming units—spleen, culture, and erythroid—by in vivo and in vitro methods. Time response of HPC was followed in mice treated at days 0, 2, and 5 with 0.75 mg 4-dmDNR/kg or 4.5 mg Dx/kg and in mice receiving 2.23 mg 4-dmDNR/kg or 3.96 mg Dx/kg twice a week for 4 weeks. The dose-survival curves of HPC for 4-dmDNR were exponential. Slight differences in sensitivity among assayed populations were seen. Although the doses of 4-dmDNR required to reduce the survival of HPC to 37% were similar or lower than those of Dx, following intermittent treatment with doses of 4-dmDNR with the same optimal antitumor activity as with Dx, 4-dmDNR seemed to have a lesser effect on hematopoietic progenitors and a greater effect on peripheral blood cells than did Dx. However, during prolonged administration 4-dmDNR appeared to be toxic at every hematopoietic level.—JNCI 1982; 68:971-976.

Researching on Dx analogues with a better toxic: therapeutic ratio, Arcamone et al. (*1*, *2*) prepared and studied 4-dmDNR ($C_{26}H_{27}NO_9CHl$; mol wt, 533.97). In mice 4-dmDNR revealed a greater potency than did Dx and proved effective also after oral administration. The toxicity pattern was similar to that induced by Dx, although with a lower cardiotoxicity in mice and rabbits. When given iv to mice, 4-dmDNR caused ventricular lesions only at doses that proved to be lethal. Although antitumoral activity and general toxicity were similar to those of Dx, the lower myocardiotoxicity made 4-dmDNR an interesting candidate for clinical studies. Therefore, we deemed worthwhile a study of the myelotoxic activity of 4-dmDNR for further information about the potential usefulness of the drug.

We performed such an evaluation by assaying the dose and time response of HPC in animals treated with a single or repeated administration of 4-dmDNR and by comparing the results with those obtained in similar experiments with Dx. This approach is justified by the useful role of hematopoietic assays in the prediction of clinical marrow toxicity of new anticancer chemotherapeutic agents (*3*).

MATERIALS AND METHODS

Mice.—(C57BL × C3H)F_1 mice, 2–3 months old, of both sexes were used as donors and recipients of bone marrow cells. Recipient mice were irradiated with a Theratron Junior cobalt-60 unit device (80 rad/min; total dose delivered, 900 rad).

Drugs.—Dx was supplied by Farmitalia Carlo Erba (Milan, Italy) in the form of a red powder. It was stored in the dark in a desiccator at 4°C and immediately before use was dissolved in normal saline (0.9% NaCl) at the working concentration. The 4-dmDNR (IMI30, batch PB 950/68), also supplied by Farmitalia Carlo Erba in the form of a powder, was stored and diluted in the same way. Structure, molecular weight, and biologic and pharmacologic activities of 4-dmDNR have been studied (*1*, *2*). Since iv administration seemed preferable for anthracyclines (*4*), both Dx and 4-dmDNR were injected into tail veins of mice.

Experimental design and rationale of adopted schedules.—Experiment A, dose-survival curves of bone marrow HPC in mice treated wtih 4-dmDNR or Dx: Five groups of 5 normal mice each received iv 1.2, 1.7, 2.9, 4.7, and 7.9 mg of the drug/kg body weight, respectively. Each dose was 5:3 of the previous one. We selected the dose range taking into account that, by previous toxicologic experiences, the LD_{50} of 4-dmDNR in the mouse at 3 months after a single iv dose is about 4.9 mg/kg body weight (*5*). Five other groups of normal mice, matched for number, sex, age, and body weight, received injections with increasing doses of Dx (2.7, 4.5, 6.8, 11.5, and 19.0 mg/kg body wt, respectively). Again, each dose was 5:3 of the previous one. The LD_{50} of Dx in the mouse at 3 months after iv injection of a single dose was 11.76 mg/kg body weight (*6*). This experimental design was aimed at an evaluation of the shape and slope of HPC survival curves obtained with 4-dmDNR, which allowed us to investigate the sensitivity of each HPC population tested with the drug. Moreover, by calculating on the obtained curves the doses of 4-dmDNR and Dx that reduced the surviving fraction of the population assayed to 37% of the normal value (D37), we were able to compare the hematologic toxicity of 4-dmDNR to that of Dx. Twenty-four hours after injection, VPRC, total leukocyte count, and the number of reticulocytes per 100 RBC in orbital sinus blood were determined; soon after, the mice were killed by cervical dislocation. Both

femurs were removed, bone marrow cellularity was checked, and bone marrow suspension was prepared. Controls that received injections with saline were subjected to equal checks.

Experiment B, time response of bone marrow HPC in mice treated with repeated doses of 4-dmDNR or Dx: In this recovery experiment, aimed to assess the effects of the drugs at varying times, a repeated treatment schedule (administration of the drug at days 0, 2, and 5) used in tests of antitumoral activity of anthracyclines was applied. In C3H mice inoculated with Gross leukemia cells this schedule was the best for Dx to develop its antileukemic activity, and it was also satisfactory for 4-dmDNR (*7*). We selected the doses of 4-dmDNR and Dx, taking into account that the above referred experiment and similar experiments on the effects of 4-demethoxy derivatives of anthracyclines against mouse tumors (*2, 5, 7, 8*) have shown that the optimal antitumor dose of 4-dmDNR is four to six times lower than that of Dx. According to this rationale, 2 groups of 40 normal mice each respectively received iv 0.75 mg 4-dmDNR/kg and 4.5 mg Dx/kg, at days 0, 2, and 5. At days 2, 3, 5, 6, 8, and 9, treated mice (5) for each group and saline-treated controls (5) were killed soon after determination of the aforementioned peripheral blood counts; assays of HPC were performed on bone marrow suspensions.

Experiment C, time response of bone marrow HPC in mice treated with 4-dmDNR or Dx for several weeks: The main problem with prolonged treatment with anthracyclines is cardiotoxicity. With this experiment we aimed to evaluate hematologic changes in mice treated for several weeks with doses of and a schedule of 4-dmDNR or Dx known to induce cardiotoxicity of a comparable degree. In mice, ventricular lesions of a significant degree have been observed after a cumulative dose of 10 mg 4-dmDNR; comparable effects have been obtained with a cumulative dose of 25–30 mg Dx (*5*). These cumulative doses were adopted in this study. Moreover, the drugs were administered according to a schedule modeled on those proposed for the study of anthracycline cardiotoxicity (*5*). The doses and the treatment schedule were therefore as follows: two administrations per week of 1.23 mg 4-dmDNR/kg body weight or of 3.96 mg Dx/kg body weight for 2 weeks, 1 week interval, and then two administrations of the same dose per week for 2 additional weeks. No study of specific toxicity apart from hematologic toxicity was made. At the end of weeks 2, 3, 4, and 5 the determinations on peripheral blood and bone marrow reported in experiments A and B were performed on 5 treated mice of each group and on 5 saline-treated controls.

Collection, preparation, and counts of samples.—Bone marrow collection and preparation of bone marrow monodispersed cell suspensions were accomplished with the usual techniques (*9*). The peripheral blood counts were done by conventional methods (*10*).

Assays for HPC.—A first aliquot of the cell suspension (obtained from femurs) was assayed for its CFU$_s$ content according to the transplant method (*11*). Nine mice, irradiated as reported above, were used as recipients for each suspension, i.e., for the bone marrow of each donor mouse. A total of 0.5 ml of cell suspension, in medium diluted to contain 4×10^4 bone marrow cells, was injected into tail vessels. The host mice were killed with ether 9 days after injection, and their spleens were excised and fixed in Tellyesniczky's fluid. The number of visible colonies was then counted: The mean number of colonies in each spleen was calculated, and the total number of CFU$_s$ per femur plus or minus the standard error was determined. A second aliquot of the cell suspension was assayed for its content of CFU$_c$ according to the in vitro method of Bradley and Metcalf (*9*). One milliliter of agar medium (α-medium) containing 1×10^5 bone marrow nucleated cells and 20% horse serum was pipetted into triplicate 35-mm Falcon petri dishes over 0.1 ml of colony-stimulating factor prepared from an extract of the uterine membrane of a pregnant mouse. After 7 days of incubation, we examined cultures by using an inverted microscope. The number of colonies that contained more than 50 cells was recorded, and the mean number of CFU$_c$ per femur plus or minus the standard error was calculated. A third aliquot of the same cell suspension was assayed for its CFU$_e$ content according to the in vitro method of Iscove et al. (*12*). Nucleated, 1×10^5 bone marrow cells were plated into duplicate 35-mm Falcon petri dishes with a 1-ml mixture of 0.8% methylcellulose–30% horse serum, and 0.25 U erythropoietin was prepared by use of plasma from phenylhydrazine-treated sheep. Only those colonies that contained more than 8 cells, as revealed by the inverted microscope after 3 days, were scored; the mean number of CFU$_e$ plus or minus the standard error per femur was then determined.

Statistical methods.—Single data points after treatment with 4-dmDNR or Dx, and in controls, were examined by the same assays on the same day to eliminate possible day-to-day variance of the assays. In time-response experiments, the values of both groups were compared between themselves and/or with control values by Student's *t*-test. Survival fractions were calculated on the absolute number of surviving HPC per femur. In charts, the contents of CFU$_s$, CFU$_c$, and CFU$_e$ per femur were normalized to those found for the corresponding controls treated with 0.9% NaCl solution. The linear *r*-value between drug doses and survival fractions and its significance were evaluated. On the dose-survival curves D37 was calculated. The analysis of variance among sensitivities to each drug of each population assayed was calculated (variance ratio F and its significance) (*13*).

RESULTS

Lethal toxicity.—In experiment A the mice were killed 24 hours after drug injection, thus preventing the possibility for evaluation of any lethality on the part of either drug. In preliminary experiments the survival rate during 10 days after treatment with three doses at days 0, 2, and 5 was 10 of 10 for animals treated with 0.75 mg 4-dmDNR/kg body weight and for animals treated with 4.5 mg Dx/kg body weight. During the 5 weeks of experiment C, no spontaneous death of 4-dmDNR-treated or Dx-treated mice was observed. Signs of general toxicity were not relevant.

Changes in peripheral blood cells, in bone marrow cellularity, and in HPC 24 hours after 4-dmDNR or Dx single injection.—The results are shown in table 1 and text-figure 1. In 4-dmDNR- and Dx-treated mice the dose-survival curves within the dose range here selected were described by a single simple

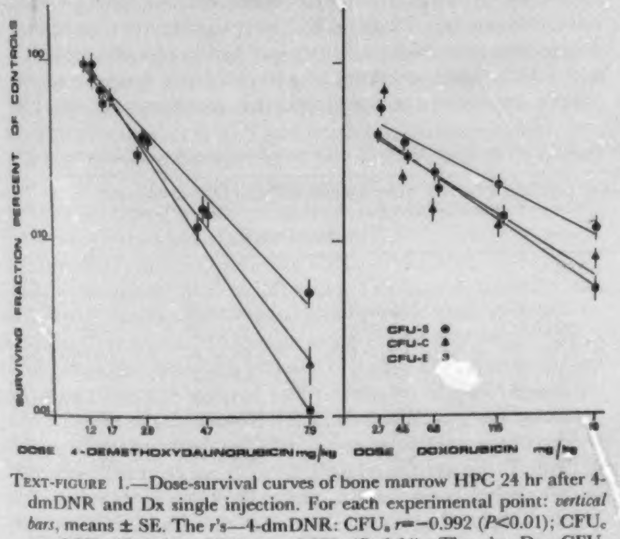
[c] Values are significantly different ($P<0.05$) from those found in Dx-treated mice.

exponential for every cell population checked (for each curve *r*, $P<0.01$). With comparison by analysis of variance of the slopes of the survival curves for 4-dmDNR, CFU$_e$ appeared significantly ($P<0.01$) more sensitive than did CFU$_c$ and CFU$_c$ were significantly ($P<0.01$) more sensitive than were CFU$_s$. CFU$_s$, CFU$_c$, and CFU$_e$ were more sensitive ($P<0.01$) than were bone marrow cells, WBC, and reticulocytes. The dose-survival curve of bone marrow cellularity indicated a higher sensitivity ($P<0.01$) than did WBC.

The D37's for each curve and the ratios D37 DX:D37 4-dmDNR are reported in table 2. In each cell population assayed, except for CFUc and CFUe, the D37's for mice treated with 4-dmDNR appeared lower than the D37's for mice treated with DX. For each drug, the D37's for WBC, reticulocytes, and bone marrow cellularity were much higher than the D37's for HPC. However, at relatively low doses, lower than 4.7 mg of the drug/kg body weight (i.e., the approximate LD_{50}), 4-dmDNR appeared to affect hematopoietic stem cells less than did Dx administered in doses that gave the same degree of leukocyte reduction.



TEXT-FIGURE 1.—Dose-survival curves of bone marrow HPC 24 hr after 4-dmDNR and Dx single injection. For each experimental point: *vertical bars*, means ± SE. The *r*'s—4-dmDNR: CFU$_s$ $r=-0.992$ ($P<0.01$); CFU$_c$ $r=-0.999$ ($P<0.01$); CFU$_e$ $r=-0.970$ ($P<0.01$). The *r*'s—Dx: CFU$_s$ $r=-0.947$ ($P<0.01$); CFU$_c$ $r=-0.842$ ($P<0.01$); CFU$_e$ $r=-0.994$ ($P<0.01$).

Effects on peripheral blood cells, bone marrow cellularity, and HPC by an intermittent treatment schedule with 4-dmDNR or Dx.—The sequence of changes in peripheral blood cell levels, bone marrow cellularity, and bone marrow CFU$_s$, CFU$_c$, and CFU$_e$ during the following intermittent administration of 4-dmDNR is reported alongside the sequence for Dx-treated mice in text-figure 2 and table 3. Following the first two doses of 4-dmDNR, the reduction in WBC, peripheral blood reticulocytes, and bone marrow cellularity was severe.

However, the administration of the third dose of the drug did not interfere with the recovery of these cells for which the levels at the end of the observation period were higher than or equal to normal. Following 4-dmDNR administration, there was a reduction in bone marrow CFU$_c$, CFU$_e$ and, to a much lower degree, CFU$_s$. A recovery followed that caused all tested cell populations to overshoot normal values. Within the time limits of this experiment, the recovery from 4-dmDNR damage was not followed by a secondary fall, and thus at the end of the observation period the 4-dmDNR-treated mice had a higher than normal endowment of hematopoietic progenitors.

In Dx-treated mice the reduction in bone marrow cellularity, WBC, and reticulocytes was less severe and that of HPC more severe than that observed in mice treated with 4-dmDNR. The recovery of CFU$_c$ was abortive, that of CFU$_e$ was short lived, and that of CFU$_s$ just reached normal values. Moreover, a secondary fall of HPC followed the initial recovery.

On the whole, in comparison of intermittent treatments with 4-dmDNR or Dx at doses that in previous experiments showed an optimal antitumor activity, 4-dmDNR seemed to have a severe effect on bone marrow cellularity and peripheral blood cells but to relatively spare CFU$_s$, thus allowing a full recovery of HPC. However, Dx appeared to affect peripheral blood cells and bone marrow cellularity to a lesser degree, but it depleted bone marrow content of progenitors. The short observation time did not allow us to study the possible late consequences of these effects.

Effects on peripheral blood cell levels, bone marrow cellularity, and HPC bone marrow content by prolonged treatment twice a week with 4-dmDNR.—As shown in text-figure 3 and table 4, during prolonged biweekly treatment 4-dmDNR severely reduced bone marrow cellularity and WBC and particularly the reticulocyte level in peripheral blood. The hematopoietic progenitor content in the bone marrow also appeared progressively depleted. After week 4, despite the continued 4-dmDNR administration, there was a recovery of CFU$_s$ to normal values and of CFU$_c$ to subnormal values. Only CFU$_e$ stayed at very low levels. In comparison, Dx, administered with a similar schedule at a cumulative dose that gave comparable cardiotoxic effects, did not affect CFU$_s$, bone marrow cellularity, WBC, or reticulocytes to a similar degree and allowed a prompter and better recovery of CFU$_c$ and CFU$_e$. During administration of both drugs, erythropoiesis appeared the most affected, as shown by the low

TABLE 4.—*Effects of prolonged biweekly treatment with 4-dmDNR and DX on peripheral blood cells and bone marrow cellularity*[a]

values attained by CFU_e and reticulocytes. The minor changes in WBC in Dx-treated mice and their early recovery in 4-dmDNR-treated animals do not reflect the severe involvement of CFU_c. On the whole, with the adopted schedule of prolonged administration, 4-dmDNR appeared to be toxic at every hematopoietic level.

DISCUSSION

The results here reported show that, like other anthracyclines (*14–18*), 24 hours after injection, 4-dmDNR in a single dose causes a dose-related reduction in bone marrow hematopoietic progenitors, either pluripotential (CFU_s) or committed to myeloid (CFU_c) or erythroid (CFU_e) differentiation. The 24-hour dose-survival curves show a "shoulder" portion, probably pointing to efficiency of cell repair of sublethal damage induced by low doses of the drug. The remaining portion fits a single exponential shape, confirming that 4-dmDNR, like Dx and other anthracyclines (*14, 15*), acts on HPC, which are in all phases of the cell cycle. There are significant differences among the slopes of the survival curves for each HPC population assayed. However, these differences, although statistically significant, are rather slight. It is well known that pluripotent stem cells (CFU_s) are mainly resting while committed progenitors (CFU_c and CFU_e) are actively proliferating in normal mice (*19*). It is therefore intriguing that 4-dmDNR, like Dx (*14*), induces a reduction of mainly resting CFU_s almost as severe as that of highly proliferating CFU_c and CFU_e.

Anthracyclines act by affecting DNA and arresting the cell cycle in G_2 (*20*), thus killing cells that are in the proliferative cycle. Although some data support the possibility that the cytotoxic activity of 4-dmDNR is determined by inhibition not only of DNA but also of RNA synthesis (*21*), on the whole 4-dmDNR shares this cycle dependency. To explain the effect on CFU_s, one must take into account that changes in bone marrow progenitor content following anticancer drug administration, while a good index of drug myelotoxicity, are due to such a complex interplay of frequently counteracting factors that a satisfactory analysis based on a single property of each progenitor population is hindered. Moreover, a major role could be played by pharmacokinetics. Experiences in tumor-bearing mice have shown high levels of 4-dmDNR in different tissues for 24–48 hours after iv injection (*22*). In this period, resting cells may be recruited to compensate for the initial damage by the drug and thus may become more sensitive to its toxic effect. Similar considerations may help to explain the erratic discrepancies between changes in HPC, bone marrow cellularity, and peripheral blood cells observed in dose-related and time-related experiments. Every proliferating phase of the hematopoietic lines may be differently affected by cycle-dependent cytotoxic drugs, and every line may develop its own compensative reactions, thus concealing part of the damage. A tentative analysis of these changes is beyond the limits of this discussion.

The 4-dmDNR is a derivative of daunorubicin, and the effects of 4-dmDNR should be better compared with those of daunorubicin. However, Dx is by far a more versatile and diffuse antitumor agent than daunorubicin, and a comparison with Dx therefore has a greater significance. The differences between 4-dmDNR and Dx on hematopoietic precursor cells are better evaluated when one takes into account that Dx is less "potent" than 4-dmDNR; i.e., Dx has the same antitumoral activity as 4-dmDNR at doses four to five times higher. However, the doses of 4-dmDNR required to reduce to 37% the survival of CFU_s, CFU_c, and CFU_e are 1.76, 0.98, and 1.08 times, respectively, those of Dx. Moreover, at low single doses 4-dmDNR produces the same or a higher degree of leukopenia and bone marrow cellularity reduction than dose Dx, but 4-dmDNR induces a significantly lower reduction in HPC. It seems that at these doses the hematopoietic suppression caused by the drug does not affect the earlier phases of hematopoiesis. Consequently, in comparison with Dx, in single low doses the new anthracycline would have a lower impact on bone marrow and allow a quicker and more complete recovery. At higher doses Dx and 4-dmDNR either have a similar effect on HPC or Dx is less toxic than 4-dmDNR.

The time-related analysis of toxic effects of 4-dmDNR also showed that low, repeated doses of the drug affected the earlier phases of hematopoiesis (i.e., the HPC compartment) less than did low, repeated doses of Dx with a comparable antileukemic activity and a lower leukopenic action. Moreover, the injurious effect of 4-dmDNR was more transitory, followed by a prompt recovery of the affected populations, thus allowing the animal to maintain its full potential for bone marrow regeneration.

The different effects of 4-dmDNR and Dx on hematopoietic cells are intriguing, but there are no clear data to explain it. Other authors who have extensively studied 4-dmDNR have pointed out a number of differences with related compounds, probably due to an increase in DNA binding, an increase in cellular uptake, or a different distribution in tissues (*5*). Uptake of 4-dmDNR by mouse embryo fibroblasts is greater than that of Dx, and 4-dmDNR induces a higher number of DNA breaks in CCRF-CEM cells in vitro (*5*). Which, if any, of these differences accounts for the observed differences remains to be defined by further studies.

The 4-dmDNR administered for a long period of time shows generally a severe toxicity on HPC that is matched by a similarly severe effect on bone marrow cellularity, WBC, and reticulocytes. However, at the end of the administration period, the hematopoietic precursors begin to recover, except for the erythroid line, which stays severely depleted. These data indicate a cumulative hematologic toxicity of repeated doses of the drug that is only partially compensated for by the hematopoietic system. In this experiment the myelotoxic activity of 4-dmDNR was also compared with that of Dx at cumulative doses of the two drugs with comparable cardiotoxicity. The 4-dmDNR showed a more severe hematologic toxicity than did Dx, but again one must take into account that a 3:2 dosage ratio was applied in this experiment, whereas the optimal antitumoral ratio is 4:5 (*2, 5, 7, 8*).

In conclusion, the new anthracycline derivative 4-dmDNR induces a dose-related reduction in HPC with slightly different effects with respect to the population assayed, has relatively little effect on HPC at low doses, but has a relatively severe cumulative effect. If 4-dmDNR were to be applied clinically, these results would suggest that single, relatively low doses could be well tolerated and could be repeated at short intervals for a few times. However, the cumulative toxicity cautions against prolonged administration.

Inheritance of Cellular Resistance to the Antitumor Agent ICRF 159 in Somatic Cell Hybrids[1]

David H. Edgar[2] *and* Andrew M. Creighton[3]

ABSTRACT—Two independently derived sublines of Syrian hamster BHK 21S cells that demonstrate resistance to the antitumor agent ICRF 159 (NSC-129943) were fused to sensitive cells in both intraspecific and interspecific crosses, and the responses of the resultant hybrids to the drug were determined. In intraspecific hybrids from crosses involving either of the sublines, resistance to ICRF 159 was expressed codominantly with the hybrid response being halfway between the parental responses. In interspecific hybrids from crosses with sensitive mouse cells, resistance was also expressed but to a lesser extent than in the intraspecific hybrids. However, subsequent passaging of an interspecific hybrid resulted in an increase in the degree of resistance, which appeared to be accompanied by a loss of telocentric mouse chromosomes. The results suggested that resistance in these lines was due to an alteration in the cellular target involved in the response to ICRF 159.—JNCI 1982; 68:977–980.

Drug resistance as displayed by somatic cells in culture can serve as a model system for the study of the changes that may accompany the emergence of drug-resistant cell populations during the chemotherapy of malignant disease and can allow for an examination of the genetic nature of the cellular events that lead to these changes. For such an examination the technique of somatic cell hybridization has been widely employed and the degree to which drug resistance is expressed in hybrids between sensitive and resistant cells has been observed to be dependent on the particular agent involved (*1*). Such variations appear to be attributable to differences in the molecular mechanisms underlying the acquisition of resistance. The level of expression of resistance in such hybrids may therefore provide clues to the mechanisms involved in cases where the molecular basis of cytotoxicity is unknown.

ICRF 159 is one of a series of bisdioxopiperazine derivatives that were originally synthesized as potential intracellularly activated chelating agents (*2*) and were shown to be active against experimental tumors in mice and rats (*3*). It has subsequently been developed as a drug for the treatment of human neoplastic disease (*4*, *5*) and more recently has found some application in the treatment of severe psoriasis (*6*).

At the cellular level, ICRF 159 has been shown to cause abnormal chromosome condensation when present at the G_2–M phase of the cell cycle (*7*), the phase at which ICRF 159 has also been shown to exert its maximum lethality as assessed by impairment of reproductive integrity (*8*). Binding studies with radioactively labeled ICRF 159 (*9*) failed to show an association with any cellular macromolecules, and the molecular mechanism(s) underlying the agent's cellular effects, including the putative role of chelation, remains unclear.

We are investigating the nature of ICRF 159-induced resistance in cultured cell lines as part of a study of the mechanism of action of this class of drugs. ICRF 159-resistant sublines of Syrian hamster cells have been isolated, following continuous culture of the parent cells in vitro in relatively low concentrations of the drug (*10*, *11*). These sublines were shown to have little or no significant cross-resistance to a wide variety of agents with known mechanisms of action and to be similar to the parent line with respect to uptake of [^{14}C]ICRF 159. Further, stable inheritance of resistance in the absence of the agent suggested that the resistant lines may have arisen by somatic mutation.

We now report the results of somatic cell hybridization experiments. These results show that resistance to ICRF 159 in these two Syrian hamster sublines is due to alterations at the genetic level and give some indication of the possible nature of these changes.

MATERIALS AND METHODS

Cell culture.—Cell culture was done in an LEEC incubator in a water-saturated atmosphere of 10% CO_2 in air at 37°C. Cells were grown routinely as monolayers on plastic petri dishes (diameter, 50 mm; A/S Nunc, Roskilde, Denmark) in DMEM supplemented with 10% FCS, which was obtained from Gibco Europe Ltd., Glasgow, Scotland. Hybrid selection was performed with essentially the culture system described by Littlefield (*12*). We used HAT (DMEM with 10% FCS to which 15 μg/ml hypoxanthine, 0.45 μg/ml aminopterin, and 10 μg/ml thymidine were added).

BHK 21S/TK$^-$ was a subline of BHK 21S (*13*), which we selected for its ability to grow in medium supplemented with 30 μg 5-bromo-2′-deoxyuridine/ml by gradually increasing the concentration of the agent in the medium and by subsequent cloning. The TK-deficient nature of the subclone was confirmed by its inability to grow in HAT. BS/159-1/HGPRT$^-$ and BS/159-4/HGPRT$^-$ were the two sublines of ICRF 159-resistant BHK 21S cells, BS/159-1 and BS/159-4, respectively, whose independent isolations

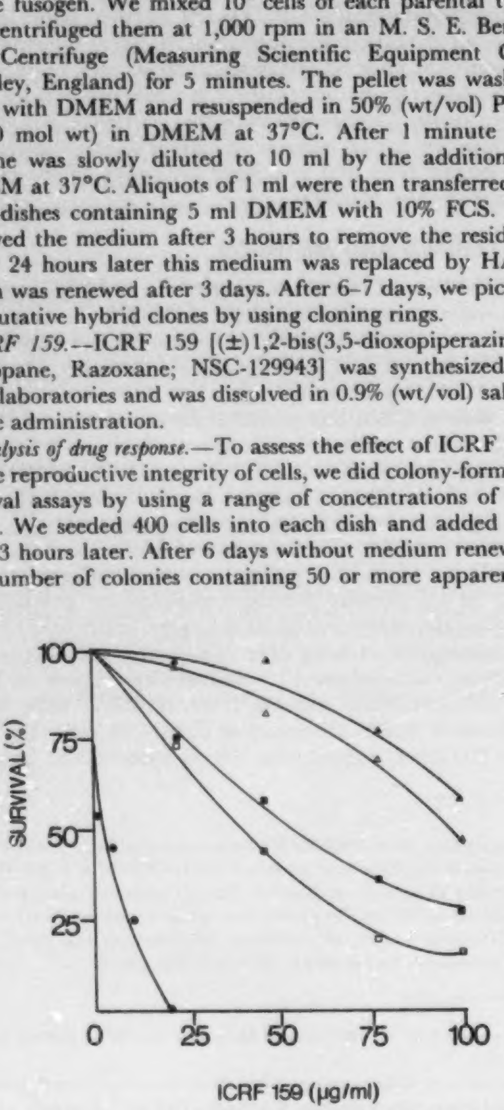
have been described previously (*10, 11*) and which had been further selected for deficiency in HGPRT by having been cloned in 10 µg 6-thioguanine/ml and by having been tested for sensitivity to HAT. The 3T3/TK⁻ mouse cells were a line of Swiss 3T3 cells that were deficient in the enzyme TK, that were able to grow in the presence of 5-bromo-2′-deoxyuridine (30 µg/ml), and that were sensitive to HAT. They were obtained from Dr. K. Quade, Department of Tumour Virology, Imperial Cancer Research Fund Laboratories, London, England.

Cell fusion.—Cell monolayers were harvested with trypsin (0.25% wt/vol), washed twice with phosphate-buffered saline, and suspended in DMEM. Cell fusion was performed in suspension with the use of PEG of molecular weight 6,000 as the fusogen. We mixed 10^6 cells of each parental type and centrifuged them at 1,000 rpm in an M. S. E. Bench Top Centrifuge (Measuring Scientific Equipment Co., Crawley, England) for 5 minutes. The pellet was washed twice with DMEM and resuspended in 50% (wt/vol) PEG (6,000 mol wt) in DMEM at 37°C. After 1 minute the volume was slowly diluted to 10 ml by the addition of DMEM at 37°C. Aliquots of 1 ml were then transferred to petri dishes containing 5 ml DMEM with 10% FCS. We renewed the medium after 3 hours to remove the residual PEG; 24 hours later this medium was replaced by HAT, which was renewed after 3 days. After 6–7 days, we picked out putative hybrid clones by using cloning rings.

ICRF 159.—ICRF 159 [(±)1,2-bis(3,5-dioxopiperazin-1-yl)propane, Razoxane; NSC-129943] was synthesized in these laboratories and was dissolved in 0.9% (wt/vol) saline before administration.

Analysis of drug response.—To assess the effect of ICRF 159 on the reproductive integrity of cells, we did colony-forming survival assays by using a range of concentrations of the agent. We seeded 400 cells into each dish and added the drug 3 hours later. After 6 days without medium renewal, the number of colonies containing 50 or more apparently normal cells was counted after they were fixed and stained with Leishman's stain. Although the drug was present throughout this period, its concentration would have fallen fairly rapidly, with a half-life of about 12 hours under the conditions of the incubation. Each dose was administered to triplicate dishes, each experiment was done three times, and the mean values were obtained. ID_{50} for a cell type was the dose required to reduce the colony-forming ability of the cells by 50% relative to the colony-forming ability of untreated control cultures, and RI_{50} was the ratio of ID_{50} for a resistant cell population compared with the ID_{50} for the sensitive cell line.



TEXT-FIGURE 1.—Response of sensitive, resistant, and hybrid Syrian hamster cells to ICRF 159 in colony-forming survival assays. Sensitive BHK 21S/TK⁻ (●), hybrid C2 (□), hybrid D2 (■), resistant BS/159-1/HGPRT⁻ (△), and resistant BS/159-4/HGPRT⁻ (▲).

TABLE 1.—*ICRF 159 ID_{50} values for sensitive and resistant Syrian hamster cells and intraspecific hybrids*

Cell type	ICRF 159 ID_{50} mean values[a]
BHK 21S/TK⁻	2.0 (1.8, 2.5, 1.7)
BS/159-1/HGPRT⁻	102 (98, 109, 99)
BS/159-4/HGPRT⁻	110 (112, 115, 103)
Hybrid C1	43 (36, 48, 45)
Hybrid C2	41 (39, 44, 40)
Hybrid C3	49 (49, 50, 51)
Hybrid D1	51 (48, 55, 50)
Hybrid D2	52 (59, 47, 50)
Hybrid D3	53 (44, 60, 55)

[a] Doses were administered at µg/ml. Mean values, calculated from the three experimental values shown *in parentheses*, are given.

Chromosome spreads.—To examine the chromosome complements of the various cell types, we treated the cells in monolayer with 0.1 µg vinblastine sulfate/ml (Sigma Chemical Co., London, England) for 2 hours, harvested them with trypsin (0.25%), made them swell using 0.07 *M* KCl for 12 minutes, and fixed them with 3:1 methanol:acetic acid before dropping them onto slides. Chromosome preparations were stained with 2% Giemsa for 10 minutes.

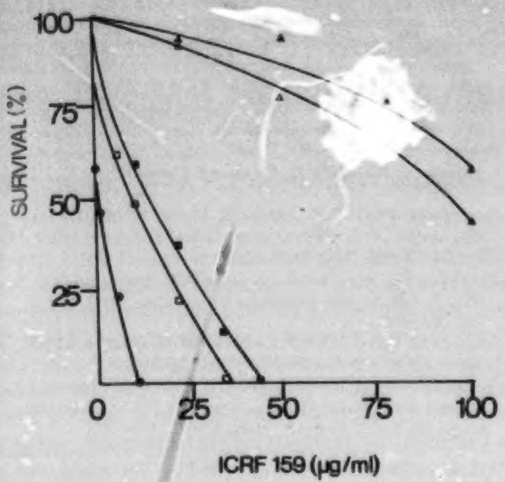
RESULTS

Expression of Resistance to ICRF 159 in Intraspecific Hybrids

To study the mode of inheritance of resistance to ICRF 159 in cell fusion experiments, we had to introduce additional markers (HGPRT⁻ and TK⁻) into the parental cell lines as described in "Materials and Methods." The introduction of these markers did not, however, result in any detectable alteration in the responses to ICRF 159.

Three clones each were picked out from intraspecific crosses between BHK 21S/TK⁻ and BS/159-1/HGPRT⁻ (C1-3) and BS/159-4/HGPRT⁻ (D1-3). The hybrid nature of the clones was confirmed by examination of their chromosome complements (mean values of 80–85 compared with ≈41 for the parent cells). Control fusions of each of the parents with itself failed to yield any colonies.

We then performed colony-forming assays, six subcultures (≈20 generations) post fusion, using a range of concentrations of ICRF 159. Text-figure 1 shows the responses of the parent cells and one representative hybrid from each of the two crosses (C2 and D2), and table 1 summarizes the ID_{50} values for all cells involved. The responses of the hybrid clones can be seen to be intermediate between those of the relevant parents, with the hybrid ID_{50} values being approx-



TEXT-FIGURE 2.—Effect of ICRF 159 on the colony-forming ability of mouse 3T3/TK$^-$ cells (●), the drug-resistant Syrian hamster cells BS/159-1/HGPRT$^-$ (△) and BS/159-4/HGPRT$^-$ (▲), and interspecific cell hybrids A1 (□) and B1 (■).

imately halfway between the parental values. Therefore, resistance to ICRF 159 in both BS/159-1/HGPRT$^-$ and BS/159-4/HGPRT$^-$ was expressed codominantly in hybrids with the sensitive parent line.

Expression of Resistance to ICRF 159 in Interspecific Hybrids

To examine the possibility that resistance to ICRF 159 in the 2 lines described was due to alteration at the genetic level, we fused both to the ICRF 159-sensitive mouse cell line 3T3/TK$^-$. A previous report (*14*) showed that for hybrids from crosses between mouse and Syrian hamster cells mouse chromosomes were preferentially lost upon serial subculture of the hybrid clones. Therefore, we wished to investigate the effect of altering the relative gene dosage on response to ICRF 159.

Three clones were picked out from each of the two crosses and were designated A1-3 (3T3/TK$^-$ × BS/159-1/HGPRT$^-$) and B1-3 (3T3/TK$^-$ × BS/159-4/HGPRT$^-$). The mean chromosome numbers of the hybrid clones lay in the range of about 100–120, being approximately the sum of the parental complements. The hybrid nature of these clones was further confirmed by the presence of both the submetacentric and metacentric chromosomes characteristic of the parent hamster cells in addition to the telocentric chromosomes characteristic of the parent mouse cells.

TABLE 2.—*ICRF 159 ID$_{50}$ values for sensitive mouse cells, resistant Syrian hamster cells, and interspecific hybrids*

Cell type	ICRF 159 ID$_{50}$ mean values[a]
3T3/TK$^-$	0.9 (0.8, 0.8, 1.1)
BS/159-1/HGPRT$^-$	102 (98, 109, 99)
BS/159-4/HGPRT$^-$	110 (112, 115, 103)
Hybrid A1	9.9 (9.3, 10.3, 10.1)
Hybrid A2	10.1 (10.6, 10.0, 9.7)
Hybrid A3	9.8 (8,9, 9.9, 10.6)
Hybrid B1	12.4 (10.9, 12.2, 14.1)
Hybrid B2	11.8 (9.9, 12.1, 13.4)
Hybrid B3	12.0 (11.8, 13.2, 11.0)

[a] Doses were administered at µg/ml. Mean values were calculated from the three experimental values shown *in parentheses*.

The parental responses to ICRF 159 with those of two representative hybrids (A1 and B1) in colony-forming survival assays are shown in text-figure 2, and the ID$_{50}$ values for parents and hybrids are listed in table 2. One can see that resistance to ICRF 159 is still expressed in the hybrids, though to a lesser extent than in the intraspecific hybrids described above.

The effect of serial subculture on the response of hybrid A2 to ICRF 159 was then investigated. Text-figure 3 shows the response in colony-forming assays of A2 at subculture 6 after cloning (A2/6) and after a further 18 subcultures in either DMEM with 10% FCS (A2/24) or in HAT (A2/24/HAT). The response of A2 to ICRF 159 was altered with time in culture with an approximately fourfold increase in the ID$_{50}$ value. The morphologies and population-doubling times of A2/24 and A2/24/HAT did not differ significantly from those of A2/6, but the mean chromosome numbers had dropped from 105 to 83 and 87, respectively. Although a full karyotypic analysis was not attempted, the reduction of metacentric (positive hamster) chromosomes from a mean of 30 to 25 and 26, respectively, suggested that the differences may be more attributable to telocentric mouse chromosome loss.

DISCUSSION

The genetic origins of various drug-resistant cellular phenotypes in vitro have been established by application of a variety of criteria such as stable inheritance, altered gene products, and the mapping of drug resistance to a particular chromosome (*15*). In such mapping, the preferential loss of, for example, human chromosomes in human-mouse somatic cell hybrids (*16*) has proved to be valuable. In this report we have used mouse-hamster hybrids, which had been shown previously (*14*) to lose mouse chromosomes preferentially to establish the genetic nature of hamster cell variants resistant to the antitumor agent ICRF 159.

Resistance was shown to be codominantly expressed in intraspecific hybrids (text-fig. 1). This result provides clues to the possible underlying mechanisms of resistance. It excludes, for example, the possibility that resistance is due to the loss of a cellular function since mutants of this type, when fused to parent sensitive cells, give rise to hybrids also sensitive to the agent in question (*17*, *18*); i.e., the resistant phenotype is then recessive. Codominant expression of resistance is often associated with an alteration in a drug-specific target, resulting in a lowered affinity of the target for the drug. Thus in the hybrids that possess both the sensitive and resistant targets the level of response to the agent is intermediate. Examples of this nature have been demonstrated with alteration of (Na, K)-ATPase (*19*) and tubulin (*20*) in cells resistant to ouabain and Colcemid, respectively.

Since resistance to ICRF 159 is not the result of impaired drug uptake (*10*), we suggest that it may be the result of an alteration in a target molecule involved in response to the agent. This putative target is presumably involved in normal cell cycle traverse control, since it has been shown (*21*) that the cytotoxic action of ICRF 159 is closely related to a characteristic perturbation of the cell cycle.

The results of the interspecific hybridization experiments show that the previously demonstrated (*14*) preferential loss of mouse chromosomes by the 24th subculture results in an increase in the level of resistance to ICRF 159 (text-fig. 3). The underexpression of resistance in the early stages (text-fig. 2) could be explained if preferential expression of the mouse drug-specific target was postulated. This kind of preferential expression occurs in one of three enzymes, lactate dehydrogenase, viewed in such hybrids (*14*). The subsequent increase in the RI_{60} of hybrid A2 could well be a reflection of an increase in the ratio of resistant hamster targets to sensitive mouse targets, which is in turn due to an increase in the ratio of hamster to mouse chromosomes coding for the targets. We are currently attempting to isolate human cell lines resistant to ICRF 159, with the intention of extending this analysis to the mapping of resistance to a single human chromosome in human–rodent hybrids.

Further Studies on the Relationship Between Allotransplantability and the Presence of the Cell Surface Glycoprotein Epiglycanin in the TA3-MM Mouse Mammary Carcinoma Ascites Cell[1,2,3]

Scott C. Miller,[4] John F. Codington,[5,6] *and* George Klein[7,8]

ABSTRACT—The loss of strain specificity in the TA3-St mammary carcinoma ascites cell during passage in ascites form in diseased syngeneic strain A mice was confirmed by the observation that TA3-MM/2 ascites cells were capable of progressive growth in 7 foreign mouse strains. Support for the hypothesis that allotransplantability in the TA3-MM lines may be due to masking of cell surface histocompatibility H-2^{a} antigens by large glycoprotein (epiglycanin) molecules was obtained from the finding that the capacity of the TA3-MM/2 ascites cell to absorb anti-H-2^{a} antibody was several times less than that of the parent TA3-St ascites cell, although it was greater than the capacity of the non-strain-specific TA3-Ha line. Further support for the location of epiglycanin molecules at the cell surface was obtained by transmission electron-microscopic observation of a high concentration of filamentous structures, usually 20–40 nm long, but often extending to 200–300 nm length at the TA3-MM/2 cell surface. Similar structures were also observed at the TA3-Ha cell surface but were not observed at the surface of the TA3-St ascites cell, a cell known to contain no detectable epiglycanin. Epiglycanin molecules, obtained by two different methods from TA3-MM/1, TA3-MM/2, and TA3-Ha ascites cells, were shown to be similar with respect to their capacities to inhibit the binding of ^{125}I-labeled epiglycanin to its antibody, induced in the rabbit by TA3-Ha ascites cells in a radioimmunoassay.—JNCI 1982; 68:981–988.

Two transitions from strain specificity to nonstrain specificity in the spontaneously derived TA3 mammary carcinoma ascites tumor have been reported (*1–3*). The first transition was observed in the strain-specific ascites subline TA3-Ha, which became allotransplantable during "routine" passage(s) in A/HeHa mice (*1*). Although the circumstances of this event or series of events were not reported, loss of strain specificity presumably occurred between in vivo passages 200 and 300 (*1*). In an effort to explain loss of strain specificity in physicochemical and morphologic terms, a wide variety of experimental procedures have been performed (*4–12*). As a result of this work, a mechanism to explain allotransplantability in the TA3-Ha ascites cell, namely, masking of cell surface histocompatability H-2^{a} antigens by large, endogenous glycoprotein (epiglycanin) molecules, has been suggested (*5, 12–15*).

A more recent event resulting in loss of strain specificity occurred in a second strain-specific subline, TA3-St, of the same tumor. In this instance, however, ascites cells were injected into A/HeHa mice infected with pneumonia-producing microorganism (*2, 3*). Within a single passage in vivo, lectin-binding sites were observed on the cell surface (*2, 3*). This phenomenon is characteristic of the new allotransplantable line and absent from the parent strain-specific line. From the new TA3-MM line, the two sublines TA3-MM/1 and TA3-MM/2 were established and differed somewhat in the composition of their cell surface glycoproteins (*2*).

The two independently derived allotransplantable lines TA3-Ha and TA3-MM differed markedly from each other in certain properties, such as cell size and chromosome numbers (*2, 3*). The common feature of the two cell lines, however, was an abundance of the large endogenous cell surface glycoprotein epiglycanin. In this paper, surface characteristics of the TA3-MM/2 subline are compared to those of the TA3-Ha and TA3-St ascites cells as observed by high-resolution transmission electron microscopy. In addition, we compared the capacity of the three cell lines to absorb antibodies to the H-2^{a} antigen and compared structural features of epiglycanin samples isolated from the two TA3-MM sublines with those of TA3-Ha epiglycanin by means of a recently described radioimmunoassay (*16*) with the use of an antibody to TA3-Ha epiglycanin.

MATERIALS AND METHODS

Cells.—The origin and characteristics of the TA3-St and TA3-Ha ascites cells have previously been described (*1, 3*). The TA3 tumor arose spontaneously as a mammary carcinoma in a female A/HeHa mouse. The two ascites sublines TA3-St and TA3-Ha were strain-specific, but after more than 200 passages in ascites form the TA3-Ha ascites cells lost their strain specificity, whereas TA3-St ascites cells remained strain-specific for more than 600 passages in ascites form in healthy strain A mice. The transition of the TA3-St ascites cell into the TA3-MM cell (*2, 3*) occurred during the passage of the TA3-St ascites cells (passage 321) into A/HeHa mice with an acute respiratory disease (*3*). Two variants, TA3-MM/1 and TA3-MM/2, which differed slightly in cell surface chemical composition, were established (*2, 3*). Cell lines were maintained by weekly passage

in A/HeJ mice (The Jackson Laboratory, Bar Harbor, Maine) with ip inocula of 10^5 TA3-MM/1, TA3-MM/2, or TA3-Ha and 10^6 TA3-St ascites cells. After 7 days, cells were collected by transperitoneal aspiration, as previously described (*3, 4*).

Electron microscopy.—The cells were prepared for electron microscopy on the day of harvest. Because the appearance of filamentous material at the cell surface by electron microscopy depends on the methods of fixation and staining, similar procedures were used on the cells in this study as were previously used (*11*). Washed cells were fixed in suspension in 2% glutaraldehyde in 0.1 *M* sodium cacodylate buffer and post-fixed for 1 hour in 1% osmium tetroxide in the same buffer. The cells were dehydrated in ethanol and embedded in Spurr's low-viscosity plastic (*17*). The sections cut for electron microscopy were stained with uranyl acetate and lead citrate and examined on a JEOL 100S electron microscope.

Allograft experiments.—Both syngeneic (A/Sn) and allogeneic (A.SW, A.CA, A.BY, C57BL/6, C3H, CBA, and DBA/2) mice were bred and housed at the Department of Tumor Biology, Karolinska Institutet Medical School, Stockholm, Sweden. Mice were given ip inoculations of 10^6 TA3-St or TA3-MM/2 cells or 10^5 TA3-Ha cells. The day of death was recorded in each case, and each mouse was examined to determine if death was attributable to tumor growth.

Absorption of anti-H^a antibody.—Seven serial dilutions (4.0–6.2×10^4 cells) and controls of each cell line in triplicates were incubated at 37°C for 45 minutes with A.CA anti-H-2^a antiserum (diluted 1:8 with RPMI-1640 medium containing 10% calf serum). After centrifugation, an aliquot of each supernatant was tested. The amount of absorbed antibody was calculated from the cytotoxic action in the presence of guinea pig complement against normal A/Sn lymph node cells as target cells (*18*). Comparison of the absorptive capacity of the three cell lines for a single pool of antiserum, expressed as the ratio of bound to free antibody [(100−P):P] was calculated according to the method of Reif (*19*). A G-value was calculated (*19*), and its reciprocal 1/G was used as a measure of the absorptive capacity of the different cell lines.

Inhibitory activities by radioimmunoassay.—The induction and characteristics of an antibody to epiglycanin are described elsewhere (*16*). Experiments for comparison of the inhibitory activities of analogous fractions of epiglycanin from TA3-MM/1, TA3-MM/2, and TA3-Ha ascites cells were performed by a radioimmunoassay (*16*). After the incubation of the inhibitor (the substance containing the antigenic determinant) and the anti-epiglycanin antiserum, the mixture was incubated with [^{125}I]epiglycanin. Activity was measured by the amount of sample required to inhibit 50% of the binding of the radiolabeled epiglycanin with the antibody.

RESULTS

Comparative Morphology of TA3-MM/2, TA3-Ha, and TA3-St Cells

Viewed by low-power transmission electron microscopy, the TA3-MM/2 (fig. 1), TA3-Ha (fig. 2), and TA3-St ascites cells (fig. 3) are generally spherical when fixed in suspension. All are characterized by cell surface projections and microvilli. At the surfaces of the TA3-MM/2 and TA3-Ha cells, the microvilli are numerous and usually straight and appear to be rigid as they extend from the cell body. On the TA3-St cell the microextensions are often curved and extend from a more irregular cell surface (fig. 3).

Cells from each of the three sublines (figs. 1–3) possess large pleomorphic eccentrically located nuclei with moderate amounts of clumpy heterochromatin. The nucleoli are usually large, and sometimes several nucleoli are seen in a nucleus. Mitochondria and some rough endoplasmic reticulum are distributed throughout the cytoplasm. A Golgi complex is usually seen near the cell center, and free ribosomes are abundant in the cytoplasm. Intracisternal virus particles and virus particles budding from the plasma membrane are seen in the cells of all three cell lines.

Comparative Studies of the Filamentous Material at the Surfaces of the TA3-MM/2, TA3-Ha, and TA3-St Cells

No morphologically distinct coat is seen at the surface of the strain-specific TA3-St cells (fig. 4). In contrast, a distinct coat is evident at the surface of similarly prepared non-strain-specific TA3-Ha ascites cells (fig. 5). This cell surface coat appears as a meshwork of fine filamentous material and usually extends to a distance of 30–50 nm or more from the plasma membrane. The cell coat is particularly evident on the microvilli of this cell.

Morphologically distinct filamentous structures are also present at the surface of the TA3-MM/2 ascites cell (fig. 6). These structures resemble the material at the surface of the TA3-Ha ascites cells (fig. 5). However, the filamentous material of the TA3-MM/2 surface is usually not as thick as that seen at the surface of the TA3-Ha cell. As for the TA3-Ha cell, the filamentous material usually extends from 20 to 40 nm from the plasma membrane and the surface coat is most conspicuous on the microvilli. Virus particles budding from the surface of TA3-MM/2 cells (fig. 7), like those budding from TA3-Ha cells (*11*), have a coat at their surfaces similar in appearance to that seen on the plasma cell membrane. In areas of high microvilli density, numerous long and very thin filamentous structures are seen bridging adjacent microvilli (fig. 8). These structures have a low electron density and often extend to 300 nm in length.

Transplantability

The TA3-MM/2 ascites cell, as well as the TA3-Ha cell, exhibited the capacity to grow progressively in ascites form in 7 foreign mouse strains and in the syngeneic strain A mouse (table 1). By contrast, the TA3-St ascites cell continued to exhibit strain-specific characteristics and grew only in the syngeneic strain A mouse.

Absorptive Capacities

The relative amounts of anti-H-2^a antibody absorbed by the TA3-MM/2, TA3-Ha, and TA3-St ascites cells are illustrated in text-figure 1. The TA3-MM/2 cells absorbed

an amount of antibody intermediate between that of the non-strain-specific TA3-Ha and the strain-specific TA3-St cells.

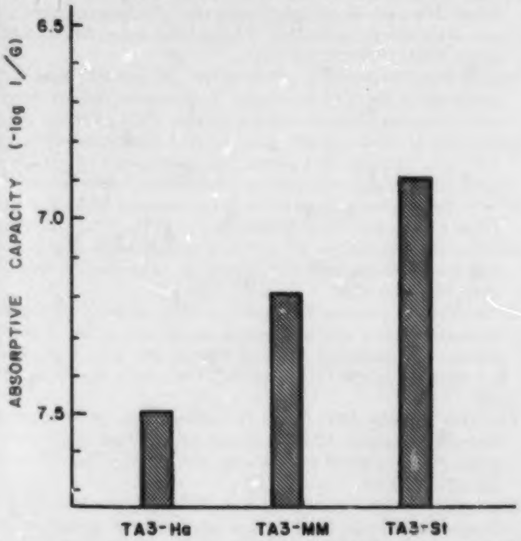
Radioimmunoassay

The capacities of epiglycanin fractions from the TA3-MM/1 and TA3-MM/2 ascites cells to inhibit the binding of [^{125}I]epiglycanin (from TA3-Ha cells) with the antibody to epiglycanin (from TA3-Ha cells) (*16*) are compared with those of similar fractions of epiglycanin isolated from the TA3-Ha ascites cell (table 2). Material cleaved from either TA3-MM/1 or TA3-MM/2 cells by proteolysis (*2*) and purified by gel filtration (fraction A) exhibited approximately the same level of activity as a fraction isolated in the same way from TA3-Ha ascites cells. A fraction shed from proliferating TA3-MM/2 cells into the ascitic fluid of syngeneic hosts and purified by gel filtration (fraction II) (*2*) exhibited somewhat greater inhibitory activity than its TA3-Ha counterpart. In each sample except one, removal of sialic acid residues with neuraminidase significantly increased the inhibitory activity.

DISCUSSION

The qualitative loss in strain specificity (table 1) that occurred in the strain-specific TA3-St ascites cell to produce the new subline TA3-MM was accompanied by both chemical and morphologic changes. Comparison of electron micrographs of the TA3-MM/2 with those of the TA3-Ha and TA3-St cell lines is made in figures 1–8. The surface of the TA3-MM/2 variant cell (fig. 1) is replete with long extended microvilli and resembles the surface of the non-strain-specific TA3-Ha cell (fig. 2) far more than it does the surface of the parent TA3-St cell (fig. 3), which is characterized by irregular ridges and folds. The TA3-MM/2 cell was found to possess a surface coat (fig. 6) with the notable appearance of filamentous material similar to that found at the surface of the TA3-Ha ascites cell (fig. 5) (*11*).

The presence of filaments (often 300 nm long) at the surface of the TA3-MM/2 cell (fig. 8) was only observed in areas in which microvilli existed in close proximity. Similar structures were seen on the surface of the TA3-Ha cell (not shown) (*11*). The existence of these filaments is probably explained by the stability afforded by the microvilli, which may serve as anchors for the thin structures, rather than by a greater abundance of this material in these areas. The appearance of the filaments depends on the details of the fixation procedure (*11*) and requires fixing first with glutaraldehyde and then with osmium tetroxide. It is probable that the long strands seen at the TA3-MM/2 cell surface (fig. 8) are composed of epiglycanin molecules, which, after glutaraldehyde fixing, exist as aggregates of sufficient diameter and electron density to be visible by electron microscopy. Isolated molecules of epiglycanin from either the TA3-MM/2 or TA3-Ha cells appear as long, thin rods, extending to approximately 500 nm (*2*). The physical characteristics of the isolated material are thus consistent with



TEXT-FIGURE 1.—Absorptive capacities for anti-H-2[a] antibody for TA3-Ha, TA3-MM/2, and TA3-St ascites cells. Values are calculated for 1/G according to Reif (*19*) and indicate the amount of antibody bound/cell when 50% of the cytotoxic activity of the antibody was bound.

TABLE 2.—*Amounts of comparable neuraminidase-treated and untreated fractions from TA3-MM/1, TA3-MM/2, and TA3-Ha ascites cells required to inhibit the reaction: [^{125}I]epiglycanin + anti-epiglycanin antibody*[a]

those of the material seen by transmission electron microscopy at the surfaces of the two allotransplantable lines. The absence of epiglycanin at the TA3-St cell surface may explain our inability to see by electron microscopy any such material at the surface of this cell.

The TA3-MM/2 ascites cell appears to be as allotransplantable as the TA3-Ha cell (table 1). It is tempting to suggest that the capacity of TA3-MM/2 ascites cells to grow progressively in ascites form in mice of foreign strains is due to masking of surface histocompatability $H\text{-}2^a$ antigens by epiglycanin molecules. It was suggested that this protective effect in the TA3-Ha ascites cell was due mainly to a physical or steric effect (*13–15*), a suggestion consistent with the size and shape (*2, 6*) and the high concentration of epiglycanin molecules at the TA3-Ha cell surface (*2, 8, 14*). With regard to the allotransplantability of the TA3-MM/2, however, other factors may be important. Although the TA3-MM/1 line possesses approximately the same number of epiglycanin molecules per cell as the TA3-Ha ascites cell (4×10^6), the TA3-MM/2 cell appears to have only 30–40% of this number (*2*). The lower capacity of the TA3-MM/2 ascites cell to absorb anti-$H\text{-}2^a$ antibody than the TA3-Ha cell (text-fig. 1) is consistent with this observation. Thus the degree of allotransplantability of the TA3-MM/2 line does not appear to be as proportionate to the epiglycanin concentration as is the in vitro absorptive capacity for anti-$H\text{-}2^a$ antibody.

Fraction II from the TA3-MM/2 cell was found to be somewhat more active as an inhibitor in the radioimmunoassay than the comparable fraction from the TA3-Ha cell (table 2). This is of interest since epiglycanin from the TA3-MM/2 cell differed in carbohydrate composition from that of the other two lines, there being a greater proportion of *N*-acetylglucosamine residues and a smaller proportion of the major carbohydrate chains, a disaccharide of a galactose residue attached by a β-linkage at position 3 of *N*-acetylgalactosamine (*8*). Since we have demonstrated that the carbohydrate moiety in epiglycanin is involved as the antigenic determinant for this antibody (*16*), the results in the radioimmunoassay suggest that epiglycanin from the TA3-MM/2 cell probably possesses at least as many antigenic structures as those of the TA3-Ha or TA3-MM/1 cells. It is not known, however, whether or not the carbohydrate composition of epiglycanin has any direct influence on the allotransplantability of the cell.

In a series of TA3-Ha/A.CA hybrid cell lines, a direct relationship appeared to exist between the degree of allotransplantability and epiglycanin concentration (*12*) with some minor exceptions. For example, the TA3-Ha/A.CA/6 line was highly allotransplantable, yet it possessed a low concentration of epiglycanin (*12*). Its concentration of cell surface sialic acid, however, was relatively large ($570\ \mu g/10^9$ cells), approximately the same as that of the TA3-Ha ascites cell (*20*). The TA3-MM/2 line possesses twice this concentration of sialic acid (*2*). Although it has been observed that cell surface sialic acid does not affect the absorptive capacity (*13*), and in general, allotransplantability is neither proportional to the amount nor to the composition of sialic acid (*20*), a combination of factors, among them the very high concentration of sialic acid, may serve to increase the allotransplantability of the TA3-MM/2 cell.

Due to the complexity of the macromolecular structures at the cell surface and their yet poorly understood interrelationships, as well as to the probable influences of other parameters such as cell morphology and physiology, it is difficult to establish a direct relationship between structure and function in cell surface glycoproteins. Nevertheless, the present studies have shown that at least in two TA3 ascites tumor lines, the TA3-MM/2 and TA3-Ha lines that had independent origins as ascites cells and are different from each other in many important cell characteristics (*2, 3*), the presence of the endogenous large cell surface glycoprotein epiglycanin is associated with allotransplantability. It is not known whether or not the presence of this glycoprotein at the cell surface actually determines or directly influences the morphology of the TA3-MM/2 and TA3-Ha cell surfaces that is manifested in numerous long and regularly spaced microvilli (figs. 1, 2). Nevertheless, the possibility that this characteristic topography of the two lines directly influences transplantation characteristics must be considered. A suggestion has been made that allotransplantability in the TA3-Ha ascites cell was due to interference in the immune response by blocking factors composed of epiglycanin and antibody (*21*). This hypothesis was based on the finding that epiglycanin shed from proliferating ascites cells was present in the serum (*21*). The most plausible explanation for allotransplantability in these cell lines, however, remains that of histocompatability (H-2) antigen masking by cell surface epiglycanin molecules. The results presented in this report are consistent with this hypothesis.

Carcinogenesis by Isomers of *N*-Nitroso-3,5-dimethylpiperidine[1,2,3]

W. Lijinsky,[4] M. D. Reuber,[4] Sandra S. Singer,[4] *and* George M. Singer[4]

ABSTRACT—The *cis*- and *trans*-isomers of *N*-nitroso-3,5-dimethylpiperidine were administered separately in drinking water solution to groups of 20 female F344 rats for 50 weeks. The concentrations of the solutions were 0.72 m*M* for the *cis*-isomer and 0.14 m*M* for the *trans*-isomer. In both groups the animals died with tumors of the upper gastrointestinal (GI) tract, mainly carcinomas of the esophagus, at about the same time. A third group of animals was given a mixture of the two isomers in the ratio of 5 *cis*:1 *trans*, and these animals died more rapidly with the same upper GI tumors. The *trans*-isomer appeared to be a more potent carcinogen than the *cis*-isomer. The 3,5-dimethyl derivative is a less potent carcinogen than nitrosopiperidine.—JNCI 1982; 68:989–991.

The great increase in carcinogenicity of NM when substituted with methyl groups in the beta positions (*1*) was ascribed to changes in the conformation of the molecule because of the two methyl groups. The *trans*-isomer of DMNM was considerably more potent than the *cis*-isomer in rats (*2*). It was of interest to know whether this effect was similar for other cyclic nitrosamines and, to this end, a similar study was undertaken of the analogous DMNP.

Initially, DMNP was prepared as a mixture of isomers by reduction of 3,5-lutidine with either Adams' catalyst and hydrogen or sodium and ethanol followed by nitrosation. By analogy with the NM, DMNP was expected to be more carcinogenic than NP. DMNP was, therefore, administered to noninbred Sprague-Dawley rats at a lower dose than that of NP. In fact, DMNP proves to be less carcinogenic than its parent, and the incidence of tumors was small. Consequently, another experiment was undertaken in F344 rats and involved administration of higher doses of DMNP alongside its two isomers, comprising the mixture, at comparable doses.

MATERIALS AND METHODS

DMNP.—This compound was prepared by catalytic reduction of 3,4-lutidine and was resolved into the *cis*- and *trans*-isomers as previously described (*3*). Their structures were ascertained by NMR spectrometry, as follows:

Cis.—NMR ($CDCl_3$): 0.95 δ (d, 3H, *syn*-3-Me, $J_{\text{Me-3ax}} =$ 6.34 Hz), 1.03 (d, 3H, *anti*-5-Me, $J_{\text{Me-5ax}} = 6.37$), 2.00 (ddd, 1H, *syn*-2-ax-H, $J_{\text{gem}} = -12.81$, $J_{\text{2ax-3ax}} = 11.66$, $J_{\text{2ax-6ax}} =$ 0.87), 3.17 (ddd, 1H, *anti*-6-ax-H, $J_{\text{gem}} = -12.70$, $J_{\text{6ax-5ax}} =$ 11.75), 4.64 (ddd, 1H, *anti*-6-eq-H, $J_{\text{gem}} = -12.70$, $J_{\text{6eq-5ax}} =$ 4.49, $J_{\text{6eq-2eq}} = 1.7$), 5.00 (ddd, 1H, *syn*-2-eq-H, $J_{\text{gem}} =$ -12.81, $J_{\text{2eq-3ax}} = 4.10$, $J_{\text{2eq-6eq}} = 1.7$).[5]

Trans.—0.89 δ (d, 3H, *syn*-3-Me, $J_{\text{Me-3H}} = 6.79$ Hz), 1.00 (d, 3H, *anti*-5-Me, $J_{\text{Me-5H}} = 6.85$), 1.57 (t, 2H, 4-H, $J_{\text{4H-3H}}$ $= J_{\text{4H-5H}} = 5.74$), 1.7–2.35 (m, 2H, 3-H and 5-H), 3.40 (dd, 1H, *anti*-6-"axial"-H, $J_{\text{gem}} = -13.23$, $J_{\text{6H-5H}} = 6.98$), 3.80 (dd, 1H, *syn*-2-axial-H, $J_{\text{gem}} = -12.97$, $J_{\text{2H-3H}} = 6.66$), 3.84 (dd, 1H, *anti*-6-axial-H, $J_{\text{gem}} = -13.23$, $J_{\text{6H-5H}} = 4.40$), 4.21 (dd, 1H, *syn*-2-"eq"-H, $J_{\text{gem}} = -12.97$, $J_{\text{2H-3H}} = 4.32$).[6]

TEXT-FIGURE 1.—DMNP.

Animal treatments.—Groups of 20 female F344 rats, 7–8 weeks old at the beginning of treatment, were housed 4/cage and given Rockland rat diet ad libitum. DMNP and its two isomers were dissolved in water, at the concentrations shown in table 1, and administered as drinking water solutions to the rats at the rate of 80 ml/cage/day (20 ml/rat) on each of 5 days a week; on the remaining 2 days tap water was given ad libitum. The rats were allowed to die naturally and were carefully necropsied. All lesions and major organs and tissues were fixed for histologic examination.

RESULTS AND DISCUSSION

In table 1 the results of treating F344 rats with DMNP or its *cis*- and *trans*-isomers are shown. The survival of the treated animals is given together with the numbers of animals with tumors of the upper GI tract. These tumors are rarely, if ever, seen in the untreated control rats continuously maintained in our colony.

Administration of a 0.88-m*M* solution of the mixture of isomers of DMNP (82% *cis*-isomer, 16% *trans*-isomer) to F344 rats for 50 weeks (a total dose of 4.4 mmol/rat) resulted in the death of all of the animals with tumors by 82 weeks. An equimolar concentration of NP given for only 28 weeks (a total dose of 2.5 mmol) resulted in the death of all of the animals with tumors by the 36th week of the experiment (*4*). In both cases, the cause of death was principally basal cell carcinomas of the esophagus (table 1). Thus it appears

[a] Died at 82 wk.
[b] Killed at 115 wk.

that the presence of the two methyl groups in both beta positions of NP reduced the carcinogenic potency considerably; the same conclusion was drawn from the experiment in Sprague-Dawley rats, although in this case the dose was lower and the treatment period was shorter (40 wk), but the number of rats with tumors of the esophagus and forestomach was small—only 4 of 15 animals. This phenomenon is the opposite of the effect of analogous methyl substitution in NM. Introduction of the methyl groups into NM resulted in a large increase in carcinogenic potency and also produced a change in the affected organ—induction of esophageal tumors instead of the liver tumors produced by NM (*1*).

The groups of rats treated with the *cis*- and *trans*-isomers of DMNP separately also died with esophageal tumors, and the survival of both groups was comparable, even though the dose of the *trans*-isomer was only one-fifth of the *cis*-isomer. Since the incidence of tumors induced was very similar, it can be concluded that the two treatments were equally effective and that, therefore, the *trans*-isomer is a more potent carcinogen than the *cis*-isomer. This finding is analogous to the finding with DMNM, the *trans*-isomer of which was considerably more effective than the *cis*-isomer in inducing esophageal tumors in rats. In these experiments, both the *cis*- and *trans*-isomers of DMNP apparently contributed to the carcinogenic effect, since the treatment with the mixture was more effective than the treatment with either isomer alone; the dose of the mixture was the sum of the doses of each isomer.

The results of a number of previous chronic tests of methyl-substituted cyclic nitrosamines in rats led to the suggestion that a rigid "chair" conformation was favorable for the induction of esophageal tumors. In this conformation, removal of the alpha axial protons is facilitated by stereoelectronic support of the carbanion by the π-system of the N-nitroso function (*5, 6*).

However, this hypothesis is not satisfactory since, in both DMNP and DMNM (*1*), the *trans*-dimethyl groups force a distortion of the chair conformation. The ring is twisted so that both methyl groups can be pseudoequatorial and A(1, 3) interactions can be minimized. A consequence of this distortion is that all four alpha protons become approximately stereochemically equivalent.

In both instances, all four alpha protons of the *trans*-dimethyl isomers are exchanged by methanolic 40% sodium deuteroxide, but those of the piperidine are exchanged much more slowly than those of the morpholine. Under the same conditions, 2 hours at 50°C, only the axial alpha protons of the *cis*-isomer of the morpholine are exchanged, but no exchange can be demonstrated in the *cis*-isomer of DMNP even after 16 hours. The most important effect of the altered conformation induced by the *trans* dimethyl groups may be to render the alpha protons more susceptible to base abstraction. Thus doubling the number of chemically reactive sites may contribute to the observed increase in carcinogenicity in rats compared with the carcinogenicity of the *cis*-isomers.

The lessening of the carcinogenicity of DMNP compared with that of NP supports our observation that the relative carcinogenic potency of NP is inversely related to their octanol-water partition coefficients (*7*).

It is likely that the critical activation of DMNP occurs in the esophagus, since in mutagenesis studies in *Salmonella typhimurium* with a rat liver microsomal preparation for activation, there was no detectable quantitative difference in activity between the *cis*- and *trans*-isomers (*8*).

Effect of 7,12-Dimethylbenz[*a*]anthracene on Production and Action of Gamma Interferon[1,2,3]

Karen A. Colemboski,[4,5] Debra K. D. DeLor,[4] Uldis N. Streips,[4] *and* Gerald Sonnenfeld[4,6,7]

ABSTRACT—Spleens were removed from Swiss Webster mice, and cultures of spleen cells were prepared. Gamma (type II immune) interferon (IFN) production was induced in these cells by addition of the purified protein form of phytohemagglutinin (PHA-P) to the cultures. When 7,12-dimethylbenz[*a*]anthracene (DMBA) was added to the cultures either before or after addition of PHA-P, the production of gamma IFN was inhibited. The degree of inhibition was greater when the cells were treated with DMBA before addition of PHA-P. In experiments to determine the effects of DMBA on the antivirus activity of previously prepared gamma IFN preparations, DMBA was either added to target cells before the addition of exogenous gamma IFN or mixed together with exogenous gamma IFN. In both cases, the antivirus activity of this exogenous gamma IFN was not affected. These data suggest that DMBA treatment can inhibit the production but not the antivirus activity of murine gamma IFN.—JNCI 1982; 68:993–996.

The production of rat and mouse fibroblast (alpha–beta) IFN in tissue culture has been shown to be inhibited by pretreatment of the cultures with various carcinogens (*1–5*). These carcinogens include benzo[*a*]pyrene, aflatoxin B$_1$, 2-aminofluorene, chloroacetaldehyde, and DMBA (*1–5*). Weakly carcinogenic analogues of these chemicals had no effect on alpha–beta IFN induction. In these experiments a wide variety of alpha–beta IFN inducers were used, including viruses and polyriboinosinic-polyribocytidylic acid (*1–5*). The carcinogen treatment had no effect on virus replication or on the viability of the cell cultures.

An additional class of IFN has also been described (*6*). Gamma (type II immune) IFN is a lymphokine produced by lymphoid cells as part of a cell-mediated immune response (*6–8*). The present study was done to determine if the production and action of gamma IFN could also be affected by treatment of cells with the potent carcinogen DMBA.

The results of these experiments suggest that the production of gamma IFN by mouse spleen cells was inhibited by pretreatment of the cells with DMBA. In addition, gamma IFN production was also inhibited, but to a lesser extent, when DMBA treatment was withheld until after the cells were stimulated to produce IFN. Addition of DMBA to target cells prior to or together with addition of exogenous gamma IFN did not affect the antivirus activity of the IFN.

MATERIALS AND METHODS

Mice.—Female Swiss Webster mice 6–8 weeks old were obtained from Laboratory Supply Co., Indianapolis, Ind. These mice are potent producers of gamma IFN (*9*).

Chemicals.—DMBA was obtained from Eastman Organic Chemicals, Rochester, N.Y. DMSO and acetone were obtained from J. T. Baker Chemical Co., Phillipsburg, N.J. Ethanol was obtained from Aaper Alcohol and Chemical Co., Louisville, Ky.

Gamma IFN production.—Production experiments: Gamma IFN was produced by stimulation of murine spleen cells with PHA-P (Difco Laboratories, Inc., Detroit, Mich.) (*10*). Cultures of 5×10^6 spleen cells were prepared in 1 ml of RPMI-1640 medium (GIBCO, Grand Island, N.Y.) supplemented with 1% fetal bovine serum and 5×10^{-5} *M* 2-mercaptoethanol. Cell viability (live cells/total cells) was determined by trypan blue dye exclusion. PHA-P (34 μg) was added to each culture, and the cultures were allowed to incubate at 37°C for 3 days in 5% CO$_2$. Culture supernatants were harvested and contained the gamma IFN activities. This IFN has been shown to be gamma IFN because of its pH 2 sensitivity, 56°C resistance, and anti-alpha–beta IFN serum resistance (*7*).

Action experiments: Pools of murine gamma IFN were produced by tuberculin (Jensen-Salsbery Laboratories, Kansas City, Mo.) challenge of mice sensitized previously with *Mycobacterium bovis* strain BCG (*7*). The IFN activity was in the serum.

IFN assay.—Antivirus titers were determined by plaque reduction on mouse L-929 cells with the use of the Indiana strain of vesicular stomatitis virus (*11*). The antivirus titer corresponded to the reciprocal of the greatest dilution of test sample that reduced virus plaques by 50%. In this assay, one IFN antivirus unit equals 0.88 NIH G-002-904-511 reference units.

Statistical analysis.—The data were analyzed by means of Student's *t*-test.

ABBREVIATIONS USED: DMBA=7,12-dimethylbenz[*a*]anthracene; DMSO=dimethyl sulfoxide; IFN=interferon(s); PHA-P=purified protein form of phytohemagglutinin.

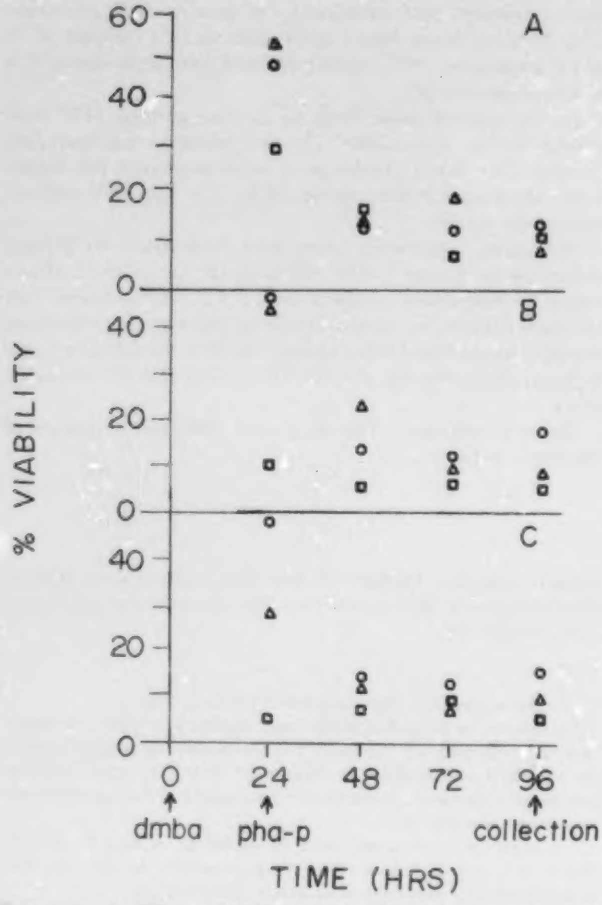
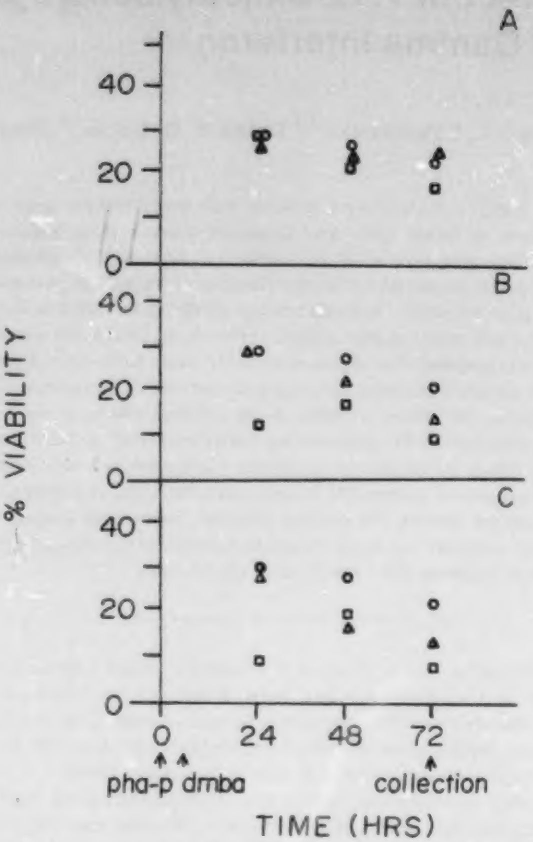
RESULTS

Effect of DMBA on the Viability of Spleen Cells

DMBA was dissolved in DMSO. DMSO was an acceptable solvent because it did not affect the viability of the spleen cells as determined by trypan blue dye exclusion (text-figs. 1, 2). Ethanol and acetone were not useful as solvents because they were toxic to the cells in the concentrations required (data not shown). Lower concentrations of DMBA had little effect on the viability of the cells, whether or not they were added before or after stimulation of gamma IFN production with PHA-P (text-figs. 1, 2). High concentrations of DMBA decreased viability of the spleen cells by a small amount at the commencement of the culture (text-figs. 1, 2). A minimal effect was observed on the viability of the cells at the termination of the culture, the time of maximal gamma IFN production (text-figs. 1, 2).



TEXT-FIGURE 1.—Effect on viability of spleen cells of addition of DMBA 24 hr prior to stimulation of cultures with PHA-P. ○=PHA-P only added; △=PHA-P and DMSO only added; □=PHA-P+DMBA in DMSO added. 1A) 8 μM DMBA in 0.2% DMSO. 1B) 40 μM DMBA in 1% DMSO. 1C) 80 μM DMBA in 2% DMSO. Viabilities at the commencement of cultures were 90–95%. Viabilities were determined by counting 200 cells and by determining the number of viable (nonstaining) cells per total cells counted at each time interval.



TEXT-FIGURE 2.—Effect on viability of spleen cells of addition of DMBA 4–5 hr after stimulation of cultures with PHA-P. ○=PHA-P only added; △=PHA-P and DMSO only added; □=PHA-P+DMBA in 0.2% DMSO added. 2A) 8 μM DMBA in 0.2% DMSO. 2B) 40 μM DMBA in 1% DMSO. 2C) 80 μM DMBA in 2% DMSO. Initial viabilities and determination of viabilities are as described in text-fig. 1.

Effect of DMBA on Gamma IFN Production

Various concentrations of DMBA were added to cultures of spleen cells. Twenty-four hours later, the DMBA was removed, cells were washed, and 34 μg of PHA-P was added to the cultures to induce gamma IFN. Three days later, the culture supernatants were harvested and assayed for antivirus activity. Since the IFN assay is a titration, a decrease of 50% or greater (or a 100% increase) in antivirus titer was required for the chemical treatment to be judged to have a reliable effect on IFN induction (*4*). No conclusions can be reached on a dose-response correlation from these data. DMBA pretreatment significantly decreased the production of gamma IFN (table 1).

PHA-P (34 μg) was added to cultures of spleen cells. Four to five hours later, several concentrations of DMBA were added to the cultures. The cultures were incubated for 3 days, and then supernatants were harvested and assayed for antivirus activity. This DMBA treatment also inhibited the production of gamma IFN (table 2).

Table 1.—*Effect of DMBA treatment of spleen cells 24 hours prior to addition of PHA-P on gamma IFN induction*

Treatment of cells	No. of expt	Anti-virus titer ± SD	Change, %[a]	P[b]
PHA-P + 0.2% DMSO	8	42±20	—	—
PHA-P + 0.2% DMSO + 8 *μM* DMBA	8	21±14	−50	<0.02
PHA-P + 1% DMSO	8	37±25	—	—

PHA-P + 2% DMSO + 80 *μM* DMBA	8	7±4	−83	<0.02

[a] Percent change as compared to cells treated with equivalent volume of DMSO. Minus indicates decrease.

[b] *P*-value as compared to cells treated with equivalent volume of DMSO.

Effect of DMBA Treatment on the Antivirus Action of IFN

L-929 cells were used as the target cells for the assay of IFN activity. L-929 cells were treated with various concentrations of DMBA. No effect of DMBA on the viability of the L-929 cells was observed with the use of trypan blue dye exclusion (text-fig. 3). In addition, no effect on cell viability was observed when DMBA was mixed with gamma IFN and applied to L-929 cells (text-fig. 3).

L-929 cells were treated with various concentrations of DMBA. Twenty-four hours later, the DMBA was removed, and the cells were washed twice with medium. Exogenous gamma IFN was added to the L-929 cells, and the IFN assay was performed as described above. No effect of DMBA treatment on the antivirus action of gamma IFN was observed (table 3).

Various concentrations of DMBA were mixed with gamma IFN preparations. The preparations were then applied to L-929 cells, and the IFN assay was done as described above. No effect of DMBA addition on the antivirus activity of the gamma IFN was observed (table 4).

Table 2.—*Effect of DMBA treatment of spleen cells 4–5 hours after addition of PHA-P on gamma IFN induction*

Treatment of cells	No. of expt	Anti-virus titer ± SD	Change, %[a]	P[b]
PHA-P + 0.2% DMSO	9	185±75	—	—

DISCUSSION

The production of alpha–beta IFN has been shown to be sensitive to a wide variety of carcinogens (*1–5*). These carcinogens include DMBA (*3*). The inhibition of alpha-beta IFN has been greatest when the cells responsible for the alpha–beta IFN production were pretreated with carcinogen before addition of the IFN inducer (*1–5*). The effect of the carcinogens did not appear to be due to a loss of cell viability (*3, 4*).

We have now demonstrated for the first time that the production of murine gamma IFN also appears to be sensitive to carcinogen treatment. Treatment of gamma IFN-producing cells with the potent carcinogen DMBA (*12, 13*) both before and after addition of PHA-P, the gamma IFN inducer, to the cell cultures resulted in inhibition of IFN induction. Inhibition of gamma IFN induction appeared to be slightly more pronounced when the DMBA was added prior to the inducer, but time of DMBA addition did not appear to play a major role in the observed effect.

Low dosages of DMBA had little effect on viability of the cell cultures. Higher dosages of DMBA partly decreased the viability of the spleen cells at the commencement of the cultures, but they did not greatly affect the viability of the cultures at the termination of the cultures when gamma IFN production was highest. Loss of cell viability, therefore, does not appear to play a major role in the effect of DMBA on gamma IFN production; however, selective loss of viability of gamma IFN-producing cells in cultures treated with high concentrations of DMBA may make some contribution to the drop in gamma IFN production, especially since DMBA treatment could have had its greatest effect on rapidly dividing cells. In addition, although no gross effects were observed on viability as determined by trypan blue dye exclusion, effects on macromolecular synthesis could have occurred. The simultaneous addition of DMBA and PHA-P to cells could have had effects on cell protein, DNA, or RNA synthesis that could have resulted in decreased gamma IFN production. Experiments to further study the mechanism of the effects of DMBA on gamma IFN induction are in progress.

Since the IFN assay is a titration, there is a twofold variability in results. Therefore, only 50% decreases can be taken as being reliable decreases from control value. It is not yet clear if any correlation can be made between dose of DMBA used and amount of decrease in gamma IFN titer greater than 50%.

DMBA treatment of cells with dosages that affect IFN induction (*3*) did not appear to significantly affect the antivirus activity of exogenously added gamma IFN. In addition, mixing DMBA directly with gamma IFN did not affect antivirus activity. Therefore, DMBA does not appear to have a direct degradative effect on gamma IFN production; i.e. DMBA-treated cells do not degrade gamma IFN, and DMBA does not inactivate gamma IFN. The exact mechanism of the effects of DMBA on IFN induction will be the subject of further study in our laboratory.

Murine Tumor Necrosis-Inducing Factor: Purification and Effects on Myelomonocytic Leukemia Cells[1,2,3]

Saul Green,[4,5] **Areta Dobrjansky,**[4] *and* **Mary Ann Chiasson**[4,6]

ABSTRACT—The tumor necrosis-inducing factor (TNF) found in sera of *Corynebacterium parvum*-treated, endotoxin-stressed BALB/C and outbred albino CD®-1 mice has been purified to a single band of protein by polyacrylamide gel electrophoresis after identification and removal of contaminating albumin and transferrin. This purified TNF has a molecular weight of 140,000, is glycoprotein in nature, and migrates on free electrophoresis as an α_2-globulin. TNF activity was continuously monitored during purification by bioassay in vitro (tumor cell lysis) and was confirmed by demonstration of induction of tumor necrosis in vivo. A single target tumor cell line, murine myelomonocytic leukemia (WEHI/3), was used in both assays. In the in vivo assay, controls were heat-inactivated samples of TNF. As additional controls, a line of TNF-resistant WEHI/3 cells was used in the in vitro assay. Results from in vivo radiolabeling of TNF-sensitive and TNF-resistant cells indicated a difference between their cytoplasmic peptide profiles. Optimal TNF production was not altered in *C. parvum*-endotoxin-treated mice by treatment with silica, a substance that is specifically toxic for macrophages. Exposure of mice to 650 rad whole-body radiation, which is not markedly damaging to macrophage elements in the reticuloendothelial system, completely abrogated the ability of the mice to produce TNF after *C. parvum*-endotoxin treatment. These findings suggest that in the sera of *C. parvum*-endotoxin-treated mice the protein that induces necrosis in tumors may not be of macrophage origin—JNCI 1982; 68:997–1003.

Numerous substances that exercise control over growth and proliferation of malignant cells exist in the sera of animals. Research in our laboratory on *C. parvum*-treated, endotoxin-stressed mice has focused on an activity in the sera that induced necrosis in transplanted tumors (*1*). This in vivo activity was ascribed to a substance designated as TNF.

Partial purification of TNF was initially accomplished by Green et al. (*2*). A fraction enriched in antitumor activity (B_{1-4}) contained glycoprotein and migrated on free electrophoresis as an α_2-globulin and on nondenaturing PAG with a retardation factor of 0.35–0.50. TNF had an apparent molecular weight of about 140,000 and contained trace amounts of galactosamine, sialic acid, glucose, and fructose. It did not contain DNA, RNA, or evidence of activity by the following enzymes: acid phosphatase, alkaline phosphatase, β-glucuronidase, glucosidase, α-galactosidase, DNAase, neuraminidase, lysozyme, or nonspecific esterases. Fraction B_{1-4} could be distinguished from certain lymphokines by several physical properties: stability to heating at 56°C; loss of activity after heating at 70°C; insensitivity to the action of trypsin, chymotrypsin, or neuraminidase; and lack of cytotoxicity for normal fibroblasts in cuture.

Fraction B_{1-4} contained four proteins (*2*), was able to induce necrosis in tumors in vivo, and was cytotoxic for mouse L-cells in vitro. Inasmuch as the cytotoxic effects of TNF were measured in two tumor cell lines, and because there is no evidence that induction of tumor necrosis in vivo and lysis of cells in culture are mediated by the same effector substance, we developed an assay using a single tumor cell line that is sensitive to the cytotoxic action of TNF in vivo and in vitro—a myelomonocytic leukemia called "WEHI/3." As a control, we developed a TNF-resistant line of the WEHI/3 cells (R-WEHI/3). Use of these cells to measure the activity of TNF and the adoption of more stringent criteria for defining TNF activity have facilitated the final purification of murine TNF.

MATERIALS AND METHODS

Mice.—Outbred albino female CD®-1 mice (30–40 g), from Charles River Breeding Laboratories, North Wilmington, Mass., and BALB/c female mice (18–20 g), bred in our own breeding facility, were used in this study.

C. parvum.—Formalin-killed *C. parvum* strain CN-6134 was obtained from Burroughs-Wellcome Co., Research Triangle Park, N.C.

Endotoxin.—*Escherichia coli* 0127:B8, lot #568487, was obtained from Difco Laboratories, Detroit, Mich.

Silica suspensions.—Quartz particles (0.5–1.0 µm in diameter) were separated from amorphous silica preparations (Sigma Chemical Co., St. Louis, Mo.) by differential centrifugation in 0.9% NaCl. Particle size was estimated by microscopic examination. The weight of the material in suspension was determined by passing a known volume of the suspension through a preweighed 0.45-µ Millipore filter

[6] We gratefully acknowledge the skilled assistance of Dr. Paul J. Higgins in performing the immunochemical and electrophoretic analyses and of Mr. Alan Alfieri in performing the radiation experiments. We thank Dr. Jerome S. Nisselbaum for his assistance in preparing the manuscript and Mr. Abraham P. Abraham for typing the manuscript.

and by drying the filter disk and reweighing it. All silica suspensions were autoclaved before use.

Whole-body radiation.—Seven days before the start of treatment with *C. parvum* (*2*), whole-body radiation at a dose rate of 122 rad/minute was given to CD®-1 mice by means of a ^{137}Cs Gammacel unit (Atomic Energy of Canada, Ltd., Ottawa, Canada). Total dose was 650 rad (*3*) for each mouse in this study.

Preparation of TNF (fraction B_{1-4}).—Glassware and solutions (where appropriate) were autoclaved at 120°C for 40 minutes. Plastics were gas sterilized with ethylene oxide for 3 hours at 120°C or were soaked in Cidex (Scientific Products, Division of American Hospital Supply Corp., McGaw Park, Ill.) for 24 hours.

TNS was prepared from *C. parvum*–endotoxin-treated mice (*2*). Partial purification of TNF from aliquots of 100 ml sterile mouse sera (200 CD®-1 mice) was accomplished by ammonium sulfate fractionation and Sephacryl-S 200 superfine gel filtration. Pooled fractions (G-200 II) were filter sterilized, concentrated by lyophilization, dialyzed free of salt, and stored frozen at −20°C. Aliquots of approximately 4 mg G-200 II protein/ml were dialyzed against Tris–glycine buffer (pH 8.6) (*4*) for 24 hours and placed on 15 ml preparative PAG in a modified Canalco electrophoresis apparatus (Miles Laboratories, Inc., Elkhart, Ind.) (*2*). Electrophoresis at 4°C was for 16 hours at 6 mA/PAG. Proteins were localized by staining one PAG with 0.02% G-250 Coomassie blue dye in 4% PCA (*5*). The TNF-containing segment, with its characteristic four-band pattern (*2*), was used as a reference, and corresponding segments containing these proteins were sliced out of the remaining unstained PAG. Proteins were extracted from the PAG by homogenization in 0.9% NaCl with the use of a Polytron (Brinkmann Instruments, Inc., Great Neck, N.Y.). The pooled supernatants were freed of PAG particles by centrifugation and filtration through 0.45-μ Millipore filters, and the supernatants were concentrated by lyophilization. This preparation was called "fraction B_{1-4}." Protein was determined by the method of Lowry et al (*6*).

WEHI/3 cells.—WEHI/3 tumor cells growing in tissue culture (*7*) were adapted to growth in mice as follows: Cells (10^7) were injected into the peritoneal cavity of each of ten 6- to 8-week-old BALB/c female mice. After 14 days the ascitic fluid containing the tumor cells was aspirated and the washed cells were counted. Viable cells (10^7; trypan blue exclusion) in 0.5 ml sterile EMEM were reinjected ip into each of 5 BALB/c mice. Cells were maintained by weekly ip transplants.

Solid WEHI/3 tumors were raised in mice by injection of 10^6 viable cells, in 0.05 ml EMEM, into the shaved ventral skin of syngeneic BALB/c mice. Well-defined tumors (0.6–0.8 cm in diameter) resulted in 6–8 days. These tumors did not regress spontaneously and if left untreated were lethal in 4–6 weeks.

WEHI/3 tumor cells were propagated in 25-cm^2 Falcon culture flasks after inoculation of 3×10^4 cells in 5.0 ml EMEM containing 10% fetal calf serum, 2 m*M* glutamine, 100 U penicillin/ml, and 100 μg streptomycin/ml. Incubation was at 37°C in 95% air–5% CO_2. Doubling time was from 14 to 16 hours. The cells were loosely adherent and were completely recovered by gentle agitation of the flasks and the medium. The growth rate of these cells in culture was not affected by as much as 100 μg of *E. coli* endotoxin/ml medium.

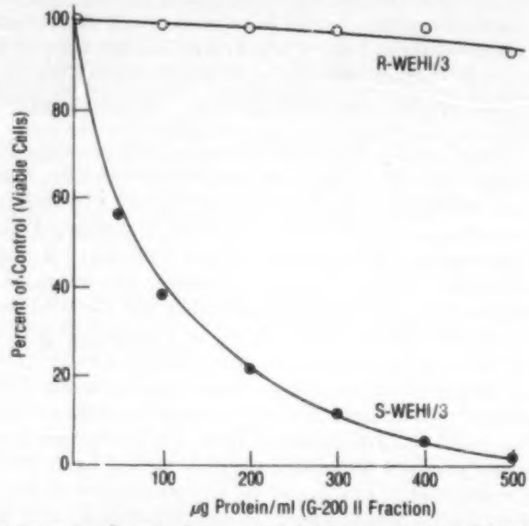
R-WEHI/3 cells.—In vitro-propagated WEHI/3 cells were selected for TNF resistance, over a 6-week period, by growth in culture medium containing progressively greater concentrations of TNF (100–500 μg G-200 fraction/ml medium). Cells were considered R to a particular concentration of TNF when the growth rate in TNF was the same as that in the control flasks. R-WEHI/3 cells were routinely propagated in medium containing 100 μg TNF. Full sensitivity to TNF could be restored by passaging R-WEHI/3 cells in TNF-free medium for at least 20 days (five passages).

TNF purification.—Methods used for final purification of TNF activity from fraction B_{1-4} are described later in the text.

TNF bioassay—In vivo activity of TNF was determined in BALB/c mice bearing 7-day intradermal transplants of WEHI/3 tumor cells, as previously described for MCA-induced fibrosarcomas in (*1*).

TNF assay in vitro.—Triplicate determination of cell viability (trypan blue exclusion) was done with the use of WEHI/3 populations exposed to graded amounts of TNF-containing fractions. After 72 hours of incubation at 37°C in a moist air–CO_2 atmosphere, cells were fully suspended in the medium by gentle agitation, and the viable cells were counted. Differences giving a probability of less than 1% ($P\leq0.01$) by Student's *t*-test for small samples were considered significant. A typical effect of graded doses of TNF on S-WEHI/3 and R-WEHI/3 cells is shown in text-figure 1.

TNF criteria.—We define TNF as the substance that conforms to the following criteria: 1) No TNF sample shall contain more than 1.0 μg endotoxin/ml as measured by the Limulus assay (*8*) (assay kit from M.A. Bioproducts, Walk-



TEXT-FIGURE 1.—Growth of cultured S-WEHI/3 cells and R-WEHI/3 cells as a function of the protein concentration of TNF (fraction G-200 II) in the culture medium. Each sample of TNF was added to duplicate culture flasks after they were inoculated with $0.6–0.7\times10^4$ cells. Viable cells were counted after 72-hr incubation. Experiment was performed three times. Results are reported as percentages of control value; no count varied from the mean by more than ±5%.

ersville, Md.). 2) An iv injection of twice the concentration of the test sample that induces necrosis (*2*) in an intradermal WEHI/3 tumor in 24 hours must result in complete tumor regression in at least 50% of the mice. 3) The dose of TNF that is lethal for tumor cells must show no toxicity for the tumor-bearing host. 4) A dose-related inhibition of S-WEHI/3 cell growth in culture must be demonstrable. 5) No growth inhibition in R-WEHI/3 cells must result after incubation with five times the LD_{100} dose of TNF for S-WEHI/3 cells. 6) No inhibition of growth in culture of normal mouse fibroblasts must result after incubation with five times the LD_{100} dose of TNF for S-WEHI/3 cells.

Immunodiffusion.—Double diffusion was done on pre-punched Immuo-Tec agarose plates (Calbiochem-Behring Corp., Los Angeles, Calif.) according to the method of Ouchterlony (*9*).

Immunoelectrophoretic analysis.—Electrophoresis was done in 1.0% agarose (wt/vol) slabs with the use of Beckman B-2 buffer (pH 8.6) at 20 mA/200 V for 1.0 hour (*10*). On completion of the electrophoretic separation, antisera troughs were filled with 50 µl of the selected antiserum, and the precipitin patterns were developed for 48 hours at 37°C. After incubation, the agarose slab was dialyzed against 0.15 *M* NaCl for 24 hours before the precipitin patterns were stained with 0.5% Amido Black 10B in 7% acetic acid.

Single radial immunodiffusion analysis.—For quantification of serum proteins at stages of TNF purification, 50–200 µl rabbit antisera to the proteins identified by immunoelectrophoresis were incorporated in 2.5 ml of 1% (wt/vol) agarose in Beckman B-2 buffer (pH 8.6) (*11, 12*). For regression analysis of protein concentrations of the test samples, antigen wells were cut and filled with 4 µl of the unknown samples; precipitin disks were measured after incubation of the agarose plates at 37°C. The specificities of these antisera were ascertained by immunoelectrophoresis, immunodiffusion, and radial immunoprecipitation (*10*).

Metabolic labeling and SDS–PAGE of WEHI/3 cellular protein.—Three days after passage, ^{3}H-labeled amino acids (5 µCi/ml of medium; New England Nuclear Corp., Boston, Mass.) were added to each WEHI/3 cell culture to obtain metabolically labeled proteins. The cells were harvested after 4 days and were washed once by centrifugation in growth medium and twice in phosphate-buffered saline. Cell pellets were lysed in 1 ml of 0.01 *M* Tris-HCl/0.5% Nonidet NP-40 (pH 7.5) (Shell Chemical Corp., New York, N.Y.). Protein determinations were by Bio-rad assay (*13*). ^{3}H-labeled amino acid-labeled WEHI/3 cellular protein (100 µg) was separated in 7.5% SDS-PAG slabs (*14*). The radioactive peptides were visualized by En^{3}Hance (New England Nuclear Corp.) treatment and autoradiography on X-Omat R film (Eastman Kodak Co., Rochester, N.Y.), followed by densitometry of the individual fluorographs.

RESULTS

Identification of Proteins in Fraction B_{1-4}

Immunoelectrophoretic and agar gel double-diffusion analysis of fraction B_{1-4} suggeted the presence of transferrin, α_2-globulin, and several polymeric forms of albumin. The presence of albumin and transferrin was confirmed by means of monospecific antisera to these mouse proteins.

An explanation for the presence of several forms of albumin in the B_{1-4} fraction of TNF was sought. Mouse albumin was purified from fraction G-200 II by preparative PAGE (*2*). PAG disks containing albumin were identified with the use of antimouse albumin by double diffusion. The protein was extracted from the PAG, and aliquots of the extract were subjected to several increasing cycles of freeze-drying and re-solution. When aliquots of these samples were run on PAGE, the stained PAG showed the presence of multiple forms of polymerized albumin. Thus the albumin in fraction B_{1-4} represents one or more of these polymeric forms.

Albumin, transferrin, and TNF were next located in preparative PAG containing an aliquot of the B_{1-4} fraction. In figure 1, the typically stained four-band TNF pattern (A, F) can be seen between disks 7 and 11. Albumin (B, C) was found in disks 10–15. Transferrin (D) was distributed between disks 10 and 11. TNF activity (E), identified with S-WEHI/3 and R-WEHI/3 cells in vitro, was found in disks 7–9. No TNF activity was found in disks 10–20. Thus the antitumor activity of the B_{1-4} fraction does not co-migrate with the proteins albumin and transferrin. Total protein in the B_{1-4} fraction used in this experiment was 5.3 mg/ml. Concentrations of albumin and of transferrin, determined by radial immunodiffusion (*11, 12*), were 1.05 and 2.65, respectively.

During these experiments we noted the presence of a cytotoxic substance for WEHI/3 cells in incompletely dialyzed extracts of blank PAG. This substance did not induce necrosis in tumors in vivo and could be completely removed by prolonged dialysis. Unfortunately, such prolonged dialysis caused a marked reduction in the TNF activity of the protein mixtures. To produce TNF free of albumin, transferrin, and this unidentified cytotoxic substance, we developed an alternative to the slicing and homogenization procedure.

Figure 1, E, shows that disk 8 contained a high titer of TNF activity but no albumin or transferrin. This disk was 4.6 cm from the origin. Accordingly, PAG 4.6 cm long were prepared. Aliquots of G-200 II in 0.12 *M* sucrose were layered on each "short" PAG, and electrophoresis was performed as previously described. After 16 hours the upper chamber of the apparatus was removed and, while keeping the PAG tubes in place, a presterilized dialysis bag containing 5.0 ml of sterile electrophoresis buffer was attached to the bottom of each PAG tube by a rubber O-ring. The apparatus was reassembled, placed in an ice-water bath, and electrophoresis was continued for 3 hours at 9 mA/PAG. The dialysis bags were removed from the PAG tubes, and their contents were pooled, concentrated, and dialyzed against 0.9% NaCl until free of buffer salts. The product was sterilized by filtration.

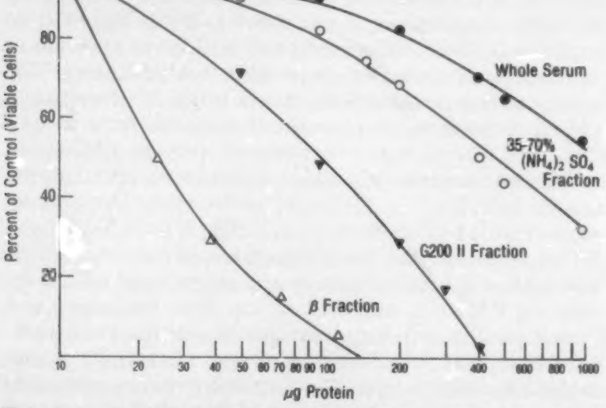
Figure 2 shows that the protein collected from the dialysis bags (called β-fraction) moved as a single band on nondenaturing PAG (C), migrated 4.6 cm from the origin, and gave a positive test for glycoproteins with periodic acid–Schiff stain (D) (*15*). No serum albumin or transferrin was detectable in this sample. This purified protein preparation migrated in free electrophoresis as an α_2-globulin, contained less than 1.0 µg/ml endotoxin (Limulus assay kit), and had a molecular weight of 140,000 as estimated by the method of Andrews (*16*). For each 24 mg of fraction G-200 II that was applied to 12 short PAG and collected by electrophoresis into dialysis bags, the protein yield was about 3.5 mg.

Text-figure 2 shows the relationship between the amount of protein in the partially purified fractions from TNS and the cytotoxic activity for S-WEHI/3 cells in culture. On the basis of the amount of protein needed to produce a reduction of 50% in the number of viable cells (*see* "Materials and Methods"), purified TNF (β-fraction) from the short PAG was about 50 times more active than the original TNS. R-WEHI/3 cells showed no inhibition from 500 μg of this purified TNF. In addition to producing lysis of WEHI/3 cells in vitro, an iv injection of 1.0 mg of this protein given to each of 7 BALB/c mice bearing intradermal WEHI/3 tumors resulted in a "+++" necrosis in each of the tumors.

The fact that WEHI/3 cells became resistant to TNF when they were grown in its presence led us to search for differences between the S-WEHI/3 and R-WEHI/3 cells. Comparison of the cytoplasmic proteins by PAGE showed a general similarity between them. However, densitometer tracings of the S-WEHI/3 and R-WEHI/3 peptides, made radioactive in vivo and identified by fluorography after SDS-PAGE separation (*see* "Materials Methods"), showed noticeable differences in the 17K and 70K regions. These observations indicate that the peptides contributing to peak complexity in these regions, as well as their relative concentrations, were different.

Role of Macrophage in TNF Production

The possibility that TNF might be of macrophage origin was suggested (*17*). During the preparation of TNS for purification of TNF, we examined the proposed role of the macrophage in TNF production in mice. We gave mice injections of crystalline silica (SiO_2), an agent specifically toxic for macrophages (*18-20*). Preliminary tests showed substantial macrophage destruction in the fluid of the peritoneal cavity of the treated mice after 3 daily ip injections (1.0 mg injection/mouse). Microscopic examination of spleen, liver, kidney, and lung sections showed silica widely distributed throughout the body tissue 5 days after administration. At this time and for 15 additional days silica-treated mice failed to clear iv-injected colloidal carbon particles.



TEXT-FIGURE 2.—Growth inhibition of S-WEHI/3 cells by fractions from TNS during purification of TNF. Samples tested were whole TNS, the 35–70% ammonium sulfate insoluble fraction, the G-200 II fraction from the S-200 gel column, and fraction β from short PAG.

TABLE 1.—*Effect of silica treatment or whole-body radiation on TNS*[a] *production in* C. parvum-*treated endotoxin-stressed CD*®*-1 mice*

Treatment[b] with:	Tumor necrosis activity in sera[c] of: Untreated mice	Silica-treated mice[d]	Whole-body irradiated mice[e]
0.9% NaCl	3/3 (–)	8/8 (–)	3/3 (–)
C. parvum alone	3/3 (–)	5/5 (–)	7/7 (–)
Endotoxin alone	3/3 (–)	3/3 (–)	4/4 (–)
C. parvum–endotoxin	8/8 (+++)	9/9 (+++)	8/8 (–)

[a] TNS was produced by method of Green et al. (*2*).

[b] By iv injection.

[c] TNF activity was determined by in vivo assay with intradermal WEHI/3 tumors as targets. (–) = no activity; (+++) = necrosis over 75% of tumor surface area in all mice 24 hr after iv injection of TNS.

[d] Treatment with silica was by daily ip injection of a suspension in 0.9% NaCl of 1.0 mg silica/ml/mouse beginning 7 days before start of *C. parvum* treatment.

[e] Whole-body radiation was delivered (as described in "Materials and Methods") 7 days before iv injection of *C. parvum*.

Silica particles (0.5–1.0 μm in diameter) were suspended in saline (to a concentration of 2.0 mg/ml) and autoclaved. For 7 days, we gave daily ip injections of 0.5 ml of the suspension to each of 25 CD®-1 female mice. This silica dose did not cause the mice to lose weight or to show signs of toxicity. We then gave the mice iv injections of *C. parvum*, followed in 7 days by endotoxin. This treatment with *C. parvum* and endotoxin normally results in the appearance of TNF in the circulation (*2*).

For the purposes of comparison a second group of mice were given 650 rad whole-body radiation 7 days before injection of *C. parvum*. At this level of radiation, there is widespread destruction of the host's blood-forming cells, with subsequent transient immunoincompetence. Circulating T-cells and B-cells were significantly reduced, but the function of fixed and circulating macrophages was only temporarily impaired (*3*).

Table 1 shows that the TNF-forming capacity of silica-treated mice was not impaired; mice that received whole-body radiation failed to respond to the priming effect of treatment with *C. parvum* and endotoxin. Although one cannot rule out the possibility that some residual macrophage helper activity remains in silica-treated mice, our findings suggest that TNF production is not primarily a macrophage function.

DISCUSSION

The activity of TNF was previously measured by an in vivo assay that depended on the induction of necrosis in intradermal MCA-induced tumors or by an in vitro assay that relied on the cytotoxicity of the sample for L-cells in culture. In the in vivo assay, false-positive results can occur from contamination of samples with bacterial endotoxin. In the in vitro assay, growth inhibition or lysis of L-cells in culture can be precipitated by a variety of lymphotoxins that do not prossess necrosis-inducing activity in vivo. Also, a lack of specificity is possible when two distinctly different tumor cell lines are used as targets (*1, 2*).

During the course of our studies on the purification and mechanism of action of TNF, development of a more specific bioassay was considered. Our finding that WEHI/3 cells were S in vivo and in vitro, and that a line of these cells could be made specifically R in vitro, allowed the development of such a bioassay. In addition, more stringent criteria were applied to the definition of the term "TNF activity." The application of these constraints and the development of a new procedure that permitted the removal of TNF from a PAG free of contamination by albumin, transferrin, or the cytotoxic PAG component resulted in the preparation of purified TNF.

In confirmation of our earlier findings (*2*) the product, which showed a single band of protein after electrophoresis on nondenaturing PAG, is an α_2-globulin that stains as a glycoprotein, has a molecular weight of 140,000 and is inactivated when heated at 70°C for 1 hour.

The cellular mechanism of TNF resistance or sensitivity is unknown. The noticeable differences we found between the peptide patterns of S-WEHI/3 cells and R-WEHI/3 cell derivatives suggest that resistance may be related to changes in several cellular peptides. Inasmuch as metabolic labeling of WEHI/3 cellular protein with ^{3}H-labeled amino acids was done in the presence of complete growth medium containing cold amino acids, the labeled bands, located by densitometer scanning, represent major and probably rapidly "turning over" protein species. Whether one or more of these changes, either qualitatively or quantitatively, results in the conference of resistance is not known. The present findings suggest that a reasonable approach to the identification of potential TNF-binding moieties would reside in a rigorous evaluation of the peptides in the approximately 17K and 70K regions.

Sera from mice made hypersensitive to endotoxin by pretreatment with *C. parvum* contain interferon, migration inhibition factor, lymphoid differentiating factor, cytotoxic activity for cultures of some tumor cell lines (but not normal cell lines), and in vivo tumor necrosis-inducing activity (*2, 21–24*). The cytotoxic and the necrotizing activities in TNS have frequently been attributed to a single endogenous factor of putative macrophage origin (*17*). A serum factor that is cytotoxic for L-cells in culture and that probably is of macrophage origin has been identified by a number of investigators (*25–28*). This substance has a molecular weight of about 50,000 and is electrophoretically heterogeneous. A cytolytic substance elaborated in vitro by endotoxin-stimulated macrophages did not induce tumor necrosis in vivo (Alexander P: Personal communication; Mannel, DN: Personal communication). Thus the possibility exists that the macrophage-derived cytotoxin contaminates the TNS and creates confusion when the in vitro assay for TNF with L-cells is used. Recently, Kull and Cuatrecasas (*29*) examined the ability of partially purified factors from TNS to induce tumor necrosis and regression in vivo. Their study clearly showed that multiple forms of cytotoxic activity were separated on gel filtration. Those proteins with molecular weights of 50,000 (or below) and 225,000 failed to induce tumor necrosis in vivo. Only the protein in the 150,000-molecular-weight range induced tumor necrosis and regression in vivo. Kull and Cuatrecasas concluded that the cytotoxic and necrotizing activities in murine tumor necrosis serum were separate and distinct entities.

Our present data support the concept that the factor in mouse serum that induces tumor necrosis in vivo is not of macrophage origin. The results of our experiments in which an acute subversion of in vivo macrophages was accomplished by injection of silica (*30–34*) showed no alteration of the TNF-forming ability of the *C. parvum*-treated, endotoxin-stressed mice. In contrast, exposure of mice to 650 rad whole-body radiation, which results in the drastic depletion of lymphoid system cells but produces only a transient decrease in the population of fixed and circulating macrophages (*3*), completely eliminated the TNF-producing capacity of the *C. parvum*-treated, endotoxin-stressed mice.

We recognize that depleting the macrophage population with silica in vivo does not result in the abrogation of all the helper activity functions of activated macrophages (*34*). However, because silica is selectively toxic for macrophages in vivo (*30, 31*), our finding that a marked reduction in macrophage activity is without influence on the production of TNF supports the concept that TNF is not a macrophage product.

Surface Antigen Expressed in Hematopoietic Cells Derived From *Fv-4*^{r} Mouse Strains[1,2]

Hiroshi Yoshikura[3,4] *and* **Takeshi Odaka**[3,5]

ABSTRACT—*Fv-4* locus controls the susceptibility of mice to ecotropic murine leukemia virus (MuLV). Antiserum against *Fv-4*$^{r/s}$ mice with BALB/c background was raised in inbred BALB/c mice. In the complement-dependent cytotoxicity test, the antiserum killed the hematopoietic cells derived from *Fv-4*$^{r/-}$ mice but not those from *Fv-4*$^{s/s}$ mice, and the genetic cross experiments located the locus controlling the expression of the target molecule of the antibody in the close vicinity of *Fv-4*. In addition, the antigenic expression of the exogenously infecting MuLV suppressed the expression of the target molecule of the antiserum. The expressions of these two antigens appear to compete with each other on the cell surface. JNCI 1982; 68:1005–1009.

The presence of *Fv-4* locus was indicated by the isolation of a mouse strain from a ddY mouse colony in Shizuoka, Japan, which was resistant to N-, B-, or NB-tropic ecotropic MuLV (*1*). The resistance allele (*Fv-4*^{r}) was dominant over the sensitive (*Fv-4*^{s}) allele, and the gene segregated independently of *Fv-1* or *Fv-2* (*1*). The introduction of *Fv-4*^{r} in AKR mice completely suppressed expression of endogenous MuLV as well as the development of thymus leukemia (*2*). A gene quite similar to *Fv-4*^{r} was widely distributed in wild mice in Asia and the United States (*3, 4*).

Fv-4w^{r}, wild mouse-derived *Fv-4*^{r}-like gene, which was recently suggested to be identical to *Fv-4*^{r} (*5*), was introduced in BALB/c mice to obtain the partially congenic strain BALB/c-*Fv-4w*$^{r/r}$ (C4W) (*5*). Because the *Fv-4*^{r} restriction was suggested to exist at the level of virus penetration of the cells (*6*), and the resistance was dominant, we suspected the existence of specific cell surface antigen in *Fv-4*^{r} mouse hematopoietic cells. To detect such antigen, we raised antibody against *Fv-4*$^{r/s}$ mouse spleen cells in BALB/c mice. This report deals with the detection of mouse *Fv-4*^{r}-specific cell surface antigen by means of a cytotoxicity test in which anti-C4W serum was used.

MATERIALS AND METHODS

Mice.—Inbred BALB/c mice were maintained in our Institute. The C4W strain has BALB/c mouse genetic background and harbors the *Fv-4*^{r} gene derived from an Fu mouse, a wild mouse trapped in Fussa in the Tokyo area. An (Fu × BALB/c)F$_2$ mouse with *Fv-4*$^{r/s}$ genotype was successively backcrossed with BALB/c mice with *Fv-4*$^{r/s}$ genotype (*5*), and the C4W mouse was established from the offspring of brother–sister matings of the seventh backcross generation. For the preparation of immunizing spleen cells, we took mice of the 11th backcross generation that were not used for mating. Mice used for genetic analysis were of the 10th and 11th backcross generations (F$_2$N$_{10}$ and F$_2$N$_{11}$).

Target of cytotoxicity test.—A spleen tumor appeared in a male *Fv-4*$^{r/r}$ mouse of the FRG strain [previously designated as G strain (*1*), which was derived from a ddY laboratory mouse colony in Shizuoka, Japan] 146 days after a single ip dose of 7,12-dimethylbenz[*a*]anthracene (*2*). The tumor was subcutaneously transplanted four times and then cultured in vitro. After examination of the culture (with fluorescent antibody technique and anti-Thy-1.2), T. Kuhara of this Institute suggested that cell line BS(43), established by T. Odaka, was a T-cell line (unpublished data).

Preparation of antiserum against Fv-4$^{r/-}$ *mouse spleen cells.*—An (Fu × BALB/c)F$_2$ mouse with *Fv-4*$^{r/s}$ genotype was serially backcrossed with BALB/c mice. The spleen cells from mice of the 11th backcross generation were pooled and used as immunogen. Inasmuch as the *Fv-4* genotype of each donor was not determined, the immunogen was derived from both *Fv-4*$^{r/s}$ and *Fv-4*$^{s/s}$ mice. The antibody was raised in 7 BALB/c female mice. At weekly intervals, the BALB/c mice were given ip injections of the cells at a dose equivalent to the cells of 1 spleen per mouse. Cytotoxicity to BS(43) cells was tested at intervals. The cytotoxic titer began to increase after four injections, and after five injections, 6 of 7 mice developed high cytotoxic titers that remained unchanged after further immunizations. The remaining mouse did not develop cytotoxic activity in the serum even after eight injections.

The following experiments were performed with pooled sera from the 6 mice that had each received five injections. Antisera: Anti-Thy-1.2 monoclonal antibody (product of hybridoma cell line F7D5) was purchased from Dainihon Seiyaku Co., Osaka, Japan. We prepared anti-Hax by giving iv injections of SIRC cells infected with Harvey murine sarcoma virus enveloped in xenotropic MuLV NZB-IU-1 (*7*) to rabbits, as described by Morse et al (*8*). We obtained antiserum against ecotropic MuLV by injecting iv undisrupted ecotropic anti-FN-2 (*9*) into the rabbits. Ecotropic

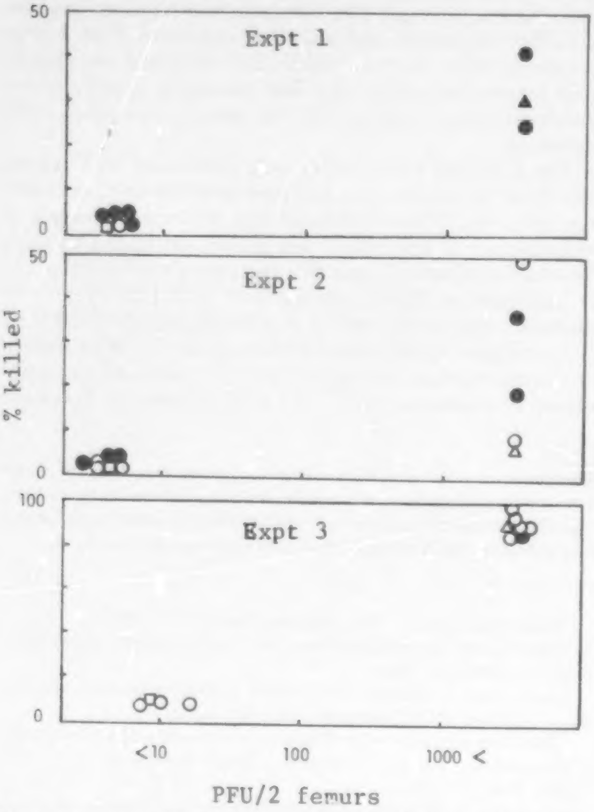
[5] We thank Dr. H. Ikeda, Department of Genetics, University of Tokyo, for preparing the anti-C4W serum with which the preliminary phase of the study was performed. We also thank Miss Sachiko Tejima and Miss Michiko Yamashita for technical assistance, and Dr. J. Yokota (on leave from Gumma University Medical School) for checking some of the cytotoxicity data.

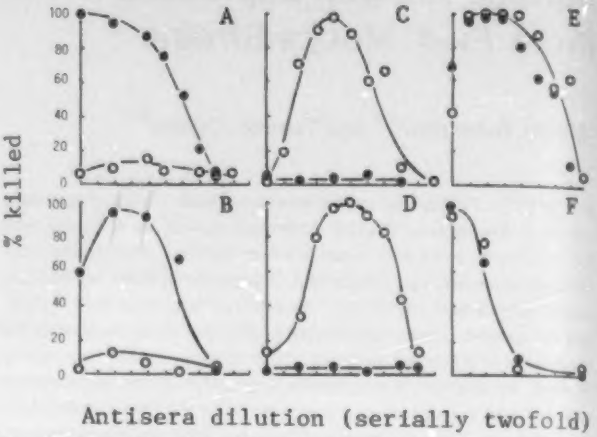
MuLV was neutralized by anti-FN-2 but not by anti-Hax. Cells infected with ecotropic MuLV were specifically killed by anti-FN-2 in the presence of complement. Anti-Hax neutralized xenotropic virus preferentially and killed all the mouse hematopoietic cells so far tested in the presence of complement, as in (*8*).

Cytotoxicity test: The complement-dependent cytotoxicity test was performed essentially in the same manner as described in (*10, 11*). Heat-inactivated antiserum was serially diluted twofold in culture medium in the multiwell tray (Flow Laboratories, Inc., Rockville, Md.) by means of the Titertek multichannel pipette (Flow Laboratories, Inc.). Each well contained 50 µl diluted serum; fresh rabbit serum in a volume of 2 µl was added as a source of complement to each well; 10 µl cell suspension ($\approx 5\times10^6$ cells/ml) was then added. The trays were incubated for 40 minutes at 37°C. The percentage of killed cells was determined by the trypan blue dye-exclusion test.

Preparation of cells for absorption of antiserum was essentially in the same manner as described in (*11*). Mice, 5–6 weeks old, were killed, and cells either from the spleen or the thymus were suspended in McCoy's 5-A medium supplemented with 7.5% heat-inactivated fetal calf serum; the cells were washed once with the medium. Cell concentration was adjusted, and the cell suspension was centrifuged to obtain a cell pellet. Anti-C4W serum, fiftyfold to a hundredfold diluted in a volume of 100 µl, was added to the tube containing the cell pellet. The cells were then suspended and incubated at 4°C for 40 minutes. The tubes containing the cells and the antiserum were centrifuged, and the supernatants were used for the cytotoxicity assay of BS(43) cells. In the linkage test (text-fig. 1), the cell number was constantly 5×10^7 cells.



TEXT-FIGURE 1.—Correlation between MuLV and the capacity of spleen cells to absorb anti-C4W antibody. PFU/2 femurs of the mice (*abscissa*) were plotted against the cytotoxicity of the serum absorbed by the spleen cells (*ordinate*). Cells were derived from male (●) and female (○) *Fv-4*$^{r/s}$ × BALB/c backcrossed mice, from male (▲) and female (△) BALB/c mice, and from female (□) C4W mice.



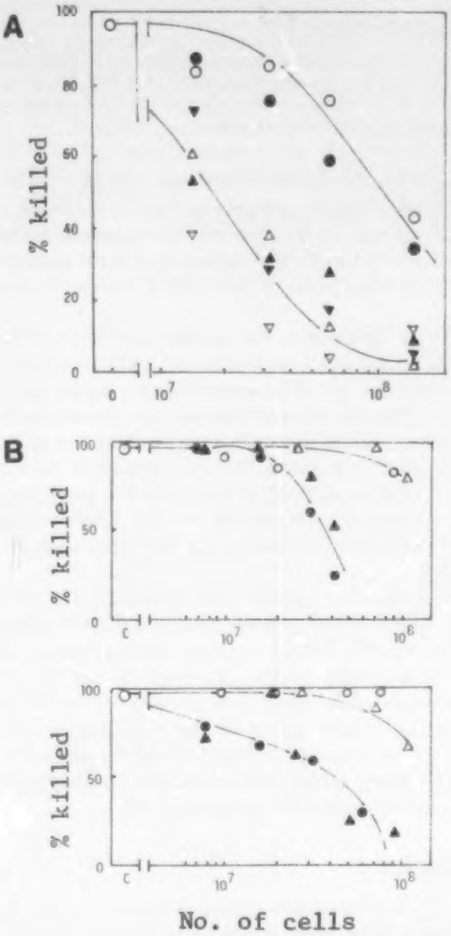
TEXT-FIGURE 2.—Complement-dependent cytotoxicity tests with BS(43) cells and F-MuLV-infected BS(43) cells. Tests were performed with anti-C4W serum (2A, 2B), anti-FN-2 (2C, 2D), anti-Hax (2E), and anti-Thy-1.2 (2F). Antisera were diluted serially twofold (from *left* to *right* in text-fig.). Highest dose was 1:30 for anti-C4W serum, 1:4 for anti-FN-2, 1:4 for anti-Hax, and 1:200,000 for anti-Thy-1.2. ● = BS(43) cells and ○ = F-MuLV-fected BS(43) cells.

RESULTS

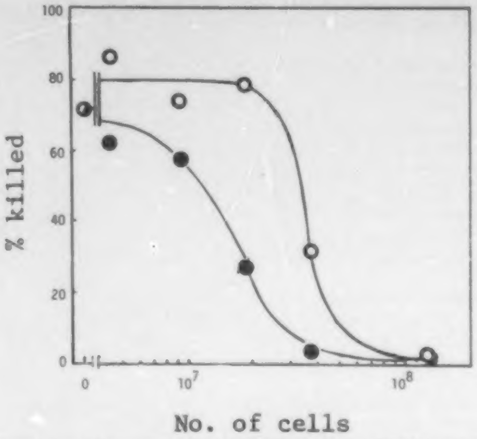
Anti-C4W serum cytotoxic activity in BS(43) cells and absorption by mouse spleen cells.—Antiserum against *Fv-4*$^{r/-}$ mouse spleen cells (anti-C4W serum) was tested for complement-dependent cytotoxicity in various cell lines: F-MuLV-derived line 745a of DBA/2 mouse origin (*12*), line T3K of DDD mouse origin (*13*), and F-MuLV-transformed nonproducer line FVTCT of BALB/c origin (*14*) were negative; mouse mammary tumor-derived line FM3A (*15*) and AKR mouse thymoma-derived line AKSL2 (*16*) were also negative. The cell line that was sensitive to the antibody was BS(43) (text-fig. 2), a line derived from an FRG mouse with *Fv-4*$^{r/r}$ genotype.

Presence of the target molecule of the cytotoxic antibody was determined by the absorption test in C4W (*Fv-4*$^{r/r}$) and BALB/c (*FV-4*$^{s/s}$) mouse spleen cells. As shown in text-figure 3A, C4W spleen cells absorped the activity much more efficiently than did BALB/c cells, indicating that the target molecule of the cytotoxic antibody was present more abundantly in the *Fv-4*$^{r/r}$ mice than in *Fv-4*$^{s/s}$ mice. However, we do not know whether a small number of the target molecules were present in BALB/c mouse cells, inasmuch as the majority of BALB/c cells absorbed the cytotoxic activity. Lack of preferential absorption by male mouse cells, relative to female cells, indicated the absence of antibody against the male antigen in the serum. Text-figure 3B shows two independent absorption experiments performed with thymus and spleen cells from C4W and BALB/c mice. The efficiency of absorption was almost identical for thymus and spleen cells, indicating that the expression of the anti-C4W target did not vary in these two cell types.

By means of the absorption test, we determined the presence of the anti-C4W target in various mouse strains. Among the mice tested, FRG (*Fv-4*$^{r/r}$), and its F_1 hybrid derived from cross-breeding with AKR (*Fv-4*$^{r/s}$), and (C57BL × Hz-IV)F_1-derived W(Hz) (*Fv-4*$^{r/r}$) absorbed the cytotoxic activity efficiently, whereas NFS, C57BL/6, DBA/2, DDD, DDD*Fv*^{r}, and NZB mice (all *Fv-4*$^{s/s}$) did not.



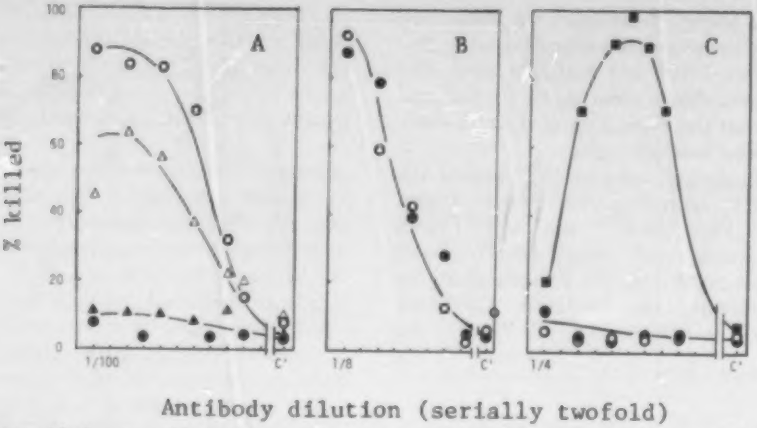
TEXT-FIGURE 3.—Absorption of anti-C4W antibody by BALB/c and C4W mouse cells. 3A) Anti-C4W serum diluted a hundredfold was absorbed by the indicated number of spleen cells and was assayed for cytotoxicity in BS(43) cells. (Percentages of cells killed were not corrected in any of the experiments reported in this paper.) Cells were derived from male (●) and female (○) BALB/c mice and from 2 male (▲, ▼) and 2 female (△, ▽) C4W mice. 3B) Two independent absorption experiments with thymus and spleen cells from C4W and BALB/c mice. Anti-C4W serum diluted fiftyfold was absorbed by thymus and spleen cells and was assayed for cytotoxicity in BS(43) cells. Cells were from the thymuses (●) and spleens (▲) of male C4W mice and from the thymuses (○) and spleens (△) of female BALB/c mice.



TEXT-FIGURE 4.—Absorption of anti-C4W serum by BS(43) cells and F-MuLV-infected cells. The hundredfold diluted anti-C4W serum was absorbed in the same manner as in text-fig. 3, and the absorbed serum was tested for complement-dependent cytotoxicity in BS(43) cells. ● = absorbed by BS (43) cells and ○ = absorbed by F-MuLV-infected BS(43) cells.

Genetic analysis.—To correlate the presence of the anti-C4W target and the *Fv-4* genotype (sensitivity to NB-tropic F-MuLV), linkage between the two markers was tested in (*Fv-4*$^{r/s}$ × BALB/c) backcrossed mice (text-fig. 1). The spleens were removed under anesthesia, and the cells were used for the absorption test: 100 µl anti-C4W serum diluted a hundredfold was absorbed by 5×10^7 cells for 40 minutes (accidentally 90 min in expt 2). The splenectomized mice were given injections of NB-tropic F-MuLV (2×10^4 PFU of XC plaque-forming MuLV and 2×10^3 spleen focus-forming units/mouse). After 10–12 days, the bone marrow cells were collected and plated on the C-182 sarcoma-negative, leukemia-positive mouse cells. The virus producers were detected by the UV–XC assay (*17*). In these experiments, we found a perfect correlation between the two markers; i.e., all of the 12 virus-susceptible mice failed to absorb the activity efficiently, whereas all of the 14 resistant mice absorbed the activity.

Suppresion of anti-C4W target by exogenous MuLV infection.—Although the above experiments suggested a close association between the *Fv-4* locus and susceptibility to anti-C4W cytotoxic antibody, we cannot state whether the antigen recognized by the antiserum was the product of the *Fv-4* locus or a product coded by an unrelated gene closely linked to *Fv-4*. We therefore examined the effect of exogenous MuLV infection on the expression of this antigen. Because the *Fv-4* locus regulates the susceptibility of mice to MuLV, a modification of the target cells could modify the expression of the antigen. F-MuLV-infected BS(43) cells were prepared by co-culturing the cells with mouse lung fibroblast line FV131 which produces F-MuLV (*18*). Although *Fv-4*$^{r/r}$ mouse-derived cells are relatively resistant to MuLV (*19*), the infection was established after 2–3 weeks of co-culture. The floating BS(43) cells were freed of the glass-adherent FV131 cells; the infected BS(43) cells were indistinguishable morphologically from the parental BS(43) cells. Text-figure 2 shows the results of the cytotoxicity tests with these two BS(43) cell lines. F-MuLV infection caused the cells to be



TEXT-FIGURE 5.—Cytotoxicity tests with thymus and bone marrow cells as targets. Antisera were diluted serially twofold (from *left* to *right* in text-fig.). C' = complement without antisera. 5A) Complement-dependent cytotoxicity of anti-C4W serum. ● = BALB/c thymus cells, ▲ = BALB/c bone marrow cells, ○ = C4W thymus cells, and △ = C4W bone marrow cells. 5B) Cytotoxicity of anti-Hax. ● = BALB/c thymus cells and ○ = C4W thymus cells. 5C) Cytotoxicity of anti-FN-2. ■ = F-MuLV-infected BS(43) cells, ● = BALB/c thymus cells, and ○ = C4W thymus cells.

sensitive to anti-FN-2 and rendered the cells resistant to the anti-C4W serum. The infected BS(43) cells remained as sensitive as the uninfected BS(43) cells to anti-Hax or to anti-Thy-1.2. The absorption test indicated that the number of expressed anti-C4W targets was reduced in the infected cells (text-fig. 4).

Thymus and bone marrow cells as targets.—Cytotoxicity test were performed with thymus and bone marrow cells. C4W-derived thymus or bone marrow cells were sensitive to anti-C4W serum, whereas BALB/c-derived cells were completely resistant. Thymus cells were relatively more sensitive than were the bone marrow cells (text-fig. 5A). Anti-Hax, killed equally thymus cells of C4W and BALB/c origins (text-fig. 5B). Anti-FN-2, which killed ecotropic MuLV-infected cells, failed to kill the thymus cells of both origins (text-fig. 5C). These experiments indicated that the anti-C4W target was expressed on the C4W mouse cell surface, but not on the BALB/c mouse cell surface, and that the anti-C4W target and the antiserum against ecotropic MuLV did not cross-react. We also noticed that thymus or bone marrow cells were more sensitive (approximately tenfold) to the anti-C4W serum than were the BS(43) cells (text-figs. 2, 5A). The greater sensitivity probably was not due to a higher expression of the antigen, because about the same number of thymus or spleen cells and BS(43) cells were required for absorption (text-figs. 3, 4).

DISCUSSION

Antibody against spleen cells derived from *Fv-4*$^{r/s}$ mice with BALB/c genetic background (anti-C4W antibody) was raised in BALB/c mice. The antibody killed, in the presence of complement, the hematopoietic cells derived from *Fv-4*$^{r/-}$ mice but not those from *Fv-4*$^{s/s}$ mice. The genetic cross experiments indicated that the *Fv-4* locus and the locus controlling the presence of the anti-C4W target are located very close to each other. If the following considerations are taken into account, these two loci could be the same: When the target cells were infected with F-MuLV, the expression of the anti-C4W target was reduced to an undetectable level, suggesting competition between the anti-C4W target and the MuLV-coded antigen in their expression on the BS(43) cell surface. In de novo infection, therefore, the C4W target present on the *Fv-4*$^{r/-}$ mouse cells may competitively interfere with adsorption of the MuLV virions by the virus receptor.

This theory agrees with the previous observation that the level of the *Fv-4* control on the MuLV infection may be the virus penetration (*6*). The situation resembles the case of C/E avian cells that showed resistance to subgroup E avian leukosis viruses (*20*). However, two phenomena apparently contradict this hypothesis: *a*) No infectious endogenous MuLV has been isolated so far from *Fv-4*$^{r/-}$ mice; inversely, *Fv-4*^{r} suppressed the expression of the AKR endogenous MuLV (*2*). *b*) Anti-FN-2 failed to cross-react with the anti-C4W target.

Numerous BALB/c spleen cells absorbed the anti-C4W antibody, which could indicate that anti-C4W targets were present in *Fv-4*$^{s/s}$ BALB/c mice though in a reduced amount. This interpretation, however, is not tenable, because *a*) BALB/c cells when used as targets were completely resistant to anti-C4W serum in the cytotoxicity test (text-fig. 5A); *b*) the immunoglobulin could be nonspecifically absorbed by many spleen cells, especially by phagocytic cells that have immunoglobulin receptors (*21*).

2′-Deoxycoformycin-Induced Hemolysis in the Mouse[1,2,3]

Ellen Spremulli, *M.D.*,[4,5,6] **Gerald W. Crabtree**, *Ph.D.*,[5] **Daniel L. Dexter**, *Ph.D.*,[4,5]
Israel Diamond, *M.D.*,[5,7] *and* **Paul Calabresi**, *M.D.*[4,5]

ABSTRACT—2′-Deoxycoformycin (dCF), a tight-binding inhibitor of adenosine deaminase, has recently been entered into clinical trials. Toxicity has included lymphopenia, seizures, coma, conjunctivitis, renal failure, and hemolysis. Mice treated with dCF on a variety of schedules exhibited massive hemolysis. Hemolysis was brief, lasting about 20 hours, and did not recur upon readministration of the drug unless readministration was delayed for at least 6 days after initial exposure, which suggests that a sensitive subpopulation of cells was selectively destroyed. Splenectomy failed to protect the animals from dCF-induced hemolysis. Administration of adenosine or 2′-deoxyadenosine without dCF did not cause hemolysis, and use of these two agents with dCF did not potentiate the observed hemolysis. ATP and dATP levels were measured in erythrocytes, and changes in levels of these nucleotides did not correspond with the development of hemolysis.—JNCI 1982; 68:1011–1014.

Recently, dCF, a tight-binding inhibitor of AdoDA (*1*), has been entered into phase I and II clinical trials. Responses have been observed in patients with mycosis fungoides and T-cell acute lymphoblastic leukemia (*2–4*). Although in initial trials the drug was well tolerated (*5*), significantly more drug toxicity was encountered in recent clinical studies. Toxic manifestations included serositis, lethargy, seizures, coma, renal failure, conjunctivitis, and hemolysis (*2–4, 6*).

Recently, Smith et al. (*7*) reported that dCF at an ip dose of 10 mg/kg in mice caused hemolysis. In the present report, we confirm their findings and present additional data that may help elucidate the mechanism responsible for the hemolysis.

MATERIALS AND METHODS

Inbred BALB/c, (C57BL × DBA/2)F_1 (BDF_1), and C57BL/6 male and female mice and outbred Swiss male and female mice were purchased from Cumberland View Farms, Clinton, Tenn. Animals were housed in the Roger Williams General Hospital Animal Care Facility (Providence, R.I.).

Obtained from Dr. John Douros (National Cancer Institute, Bethesda, Md.), dCF was dissolved in 0.9% NaCl before use. Because of the unexpected nature of the toxicity encountered, some duplicate experiments were done with the use of dCF from different lot numbers. Identity of the compound as dCF was confirmed by HPLC and by a test for AdoDA inhibition with the use of the method of Chassin et al. (*8*). Ado and dAdo were purchased from Sigma Chemical Company, St. Louis, Mo.

Splenectomy was performed on mice under ether anesthesia through a left subcostal incision. The spleen was mobilized and bluntly dissected from the pancreas, and the wound was closed with clips. Animals were rested at least 10 days after splenectomy before treatment was begun. Complete splenectomy was verified by autopsy.

The urine was examined for hemosiderin by the ferric ferrocyanide stain. Urine from several mice was pooled and centrifuged, and the sediment was stained with 2% potassium ferrocyanide and 1% hydrochloric acid.

Hemoglobin electrophoresis was performed on pooled urine specimens with the use of blood from a single mouse as a control. The hemolyzed mouse red blood cells and urine were applied to Titan III cellulose acetate plates and subjected to electrophoresis for 20 minutes at 350 V. Subsequently, the plates were stained, cleared, and scanned at 525 nm.

We treated 5 mice with 20 mg dCF/kg as a single ip dose, and we determined osmotic fragility 8 hours later using an osmotic fragility kit (Becton, Dickinson & Co., Rutherford, N.J.). For these studies, blood was incubated for 20 minutes in concentrations of saline varying from 0 to 0.85% and the concentration at which hemolysis began was recorded. The amount of hemolysis was quantitated by measurement of absorbance at 540 nm.

Pooled urine samples from mice treated with 15 mg dCF/kg were submitted to the Boston Medical Center Laboratory, Boston, Mass., and assayed for myoglobin.

We prepared blood from individual mice for HPLC by extracting 2 ml of blood with 20% perchloric acid, neutralizing the extract with potassium hydroxide, and freezing the supernatant. Levels of ATP and dATP were determined by HPLC with the use of a Varian LCS-1000 equipped with a Whatman Partisil-10 SAX column (4.6 mm×25 cm; Whatman, Inc., Clifton, N.J.). The conditions used for HPLC analysis were as described by Crabtree et al. (*9*) with detection at 254 nm.

Doses of dCF ranged from 1 to 20 mg/kg. A variety of schedules was used including a single ip or sc dose only or two doses daily, three doses daily, one dose daily for 5 days,

and one dose followed by a second dose either 3, 4, 5, 6, 7, 8, or 9 days later given either ip or sc. In addition, some animals were treated by continuous infusion over 24 hours with doses ranging from 1 to 20 mg/kg.

We accomplished continuous infusion by inserting PE10 polyethylene tubing into the lateral tail vein of the mouse. A volume of 5 ml was delivered during 24 hours by a Harvard Infusion Pump.

Ado and dAdo were dissolved in physiologic saline and administered ip or by continuous infusion both alone and in combination with dCF. Doses used included 400 mg/kg ip one time, one dose of 400 mg/kg ip daily for 3 days, and 1,000 mg/kg by continuous infusion during 24 hours.

RESULTS

Doses of dCF equal to or greater than 10 mg/kg ip or sc caused massive hemoglobinuria in some animals (table 1). Not all animals developed hemolysis; some animals that did not demonstrate hemoglobinuria on initial exposure to the drug did develop hemolysis when they were reexposed to the drug at a later date. Hemolysis occurred in both male and female animals and in several different types of mice including BDF$_1$, BALB/c, Swiss, and C57BL/6. This effect was observed with all four different lot numbers of dCF examined.

Table 1 shows the hematocrit fall observed after dCF treatment. The decrease in hematocrit was quite dramatic in some of these animals and was accompanied by visible hemoglobinemia. The observation of hemoglobinuria always correlated with a fall in hematocrit of at least 8% below that of control animals.

Hemoglobinuria, when observed, started at approximately 11 hours after an ip or sc dose of dCF and was brief; the urine generally cleared by hour 30. The animals appeared clinically healthy despite the hemoglobinuria. The identity of hemoglobin in the urine was verified by hemoglobin electrophoresis in which mouse blood was used as the standard. Tests for myoglobin and bilirubin were negative.

TABLE 1.—*Occurrence of hemoglobinuria and changes in hematocrit with increasing doses of dCF*[a]

[a] Groups of 10 female BDF$_1$ mice were treated with dCF and observed for the development of hemoglobinuria. Serial hematocrits were determined at the times indicated. Each mouse received a single ip injection. ND=not determined.

[b] With hemoglobinuria.

[c] Without hemoglobinuria.

Slides of the peripheral blood before and during the episodes of hemolysis failed to show burr cells or fragmented cells; however, multiple spherocytes were seen. Ferric ferrocyanide stain of urine sediment was negative. No changes in osmotic fragility of mouse erythrocytes were observed following dCF treatment (data not shown).

Autopsies were done on 6 mice during the episodes of hemoglobinuria; the kidneys showed no evidence of hemoglobinuric nephropathy.

Splenectomized and control BDF$_1$ female mice were given a single ip injection of dCF and observed for 72 hours. Splenectomy failed to prevent hemolysis as manifested by hemoglobinuria, hemoglobinemia, and a fall in hematocrit, which occurred between hours 10 and 15 in both groups. Spherocytes were observed in approximately equal numbers in the peripheral blood of both splenectomized and control animals.

Animals developing hemoglobinuria after an ip dose of 15 mg dCF/kg were challenged with a second dose at varying intervals. The interval between the first and second challenge ranged from 24 hours to 10 days. None of the animals that received a second dose of dCF less than 6 days after the initial treatment redeveloped hemoglobinuria. Some animals rechallenged 6 or more days after initial treatment redeveloped hemoglobinuria, which suggests that a sensitive cell population was selectively destroyed.

The following results were obtained after the specified treatments: *a*) Ten female BDF$_1$ mice were given 15 mg dCF/kg ip daily for 5 days starting on day 1. On day 2 all 10 mice had hemoglobinuria; however, by 48 hours the urine appeared normal in all these animals and remained so throughout the rest of the injection period and for a 10-day observation period thereafter. b) Four BALB/c females were given 15 mg dCF/kg ip daily for 2 days; at 24 hours 3 of 4 had hemoglobinuria, which cleared by hour 30 and did not recur despite the second injection of dCF at hour 24. *c*) Four BALB/c females were treated with 15 mg dCF/kg at hours 0 and 48. All 4 mice developed hemoglobinuria, which cleared before hour 48 and did not recur during a 4-day observation period. *d*) Five female BALB/c mice received 15 mg dCF/kg ip on day 1 through day 4; all 5 had a temporary period of hemoglobinuria, which cleared by hour 35 and did not recur. *e*) Six Swiss female mice treated with 15 mg dCF/kg ip on day 1 developed hemoglobinuria, which recurred when the second challenge was given on day 6.

When dCF was administered by 24-hour infusion, none of the animals developed hemoglobinuria. In these experiments, dCF doses ranged from 1 to 20 mg/kg, and at least 3 mice were used in each group.

Mice infused with 2,500 mg/kg of Ado or dAdo alone over 24 hours did not develop hemoglobinuria. When mice were treated with 1 mg dCF/kg ip and 1 hour later were infused with either Ado or dAdo (2,500 mg/kg) over 24 hours, the treatment was lethal; but immediately before the mice died, hemoglobinuria was not observed. Several other experiments were conducted in mice treated with combinations of dCF and either Ado or dAdo (*see* table 2). Animals receiving 1 mg dCF/kg ip followed by a 24-hour infusion of either Ado or dAdo (1,000 mg/kg) did not develop hemo-

TABLE 2.—*Hematocrit changes observed in mice treated with dCF, Ado, or dAdo*[a]

[a] Female BDF$_1$ mice were treated with dCF either as a single agent or in combination with Ado or dAdo. Hematocrits were determined at various intervals. Drugs were given either ip or by continuous infusion (*) over 24 hr. Where injections were repeated, the second injections were given 24 hr later. *Dash* indicates none given.

[b] Given two times.

globinuria. Additional studies were performed in which 4 mg dCF/kg was given ip and 1 hour later the mouse was infused with either Ado or dAdo (1,000 mg/kg) for 24 hours. Although hematocrit decreased slightly, gross hemolysis was not evident. Further experiments were conducted in which 6 mg dCF/kg was administered ip daily for 4 days; on day 2, 400 mg Ado/kg was injected ip daily for 3 days. In this group of 7 animals, none developed obvious hemoglobinuria. Serial hematocrits are recorded in table 2.

Table 3 shows the nucleotide levels of erythrocytes 18 hours after mice were treated with dCF, Ado, dAdo, or a combination of dCF and either Ado or dAdo. ATP levels did not change appreciably when mice were treated with either Ado or dAdo (400 mg/kg) or with 1 mg dCF/kg. Doses of 10 or 20 mg dCF/kg resulted in a greater than 50% decrease in ATP levels. Treatment with 1 mg dCF/kg followed by either Ado or dAdo (400 mg/kg) resulted in similar decreases in ATP levels. Measurable levels of dATP were seen with either high-dose dCF or low-dose dCF and either Ado or dAdo. ADP levels were not appreciably different from those of controls in any treatment group.

TABLE 3.—*Nucleotide profiles of mouse erythrocytes 18 hours after treatment with dCF, Ado, or dAdo*[a]

Treatment (mg/kg)	Nucleotide levels, nmol/ml packed cells			
	ADP	dADP	ATP	dATP
Saline control	81±19	—	977±64	—
Ado (400)	94±12	—	937±68	—
dAdo (400)	112±43	—	1,073±208	—
dCF (1)	82±14	—	900±145	—

dCF (1)+dAdo (200)	66±8	14±2	580±21	177±64

[a] Mice were treated ip with a single dose of dCF, Ado, dAdo, or with dCF followed 1 hr later by either Ado or dAdo. Nucleotide profiles were determined on erythrocytes 18 hr after treatment. Results are expressed as averages (with ranges) of determinations from 2 separate animals per treatment; tr=trace.

DISCUSSION

The drug dCF is a new antineoplastic agent that has recently been investigated in phase I and II clinical studies. Interest in this drug originated from its potential use *a*) as a single agent against T-cell leukemias and lymphomas and *b*) in combination with Ado analogs against a variety of solid human tumors. Clinical trials are being conducted on dCF at the Roger Williams Cancer Center and toxicity has been observed (*3*). The study reported here is part of our overall program to investigate the effects of dCF on cultured cells and in rodents to elucidate more fully the mechanisms of dCF-induced toxicity.

The doses of dCF used in this study were higher than those used by most previous investigators. Agarwal (*10*) examined AdoDA inhibition in mouse tissue after doses of dCF as high as 10 mg/kg ip and obtained complete inhibition of AdoDA in all tissues examined; lower doses (0.2 mg/kg, ip), even when given repeatedly, failed to completely inhibit AdoDA activity in spleen and small intestine.

In contrast to AdoDA-deficient children who are not anemic, patients with markedly increased AdoDA have been reported to have a hemolytic anemia (*11*). Patients with this disorder have 45- to 70-fold increases in erythrocyte AdoDA activity. The authors (*11*) postulated that the low ATP levels found in these erythrocytes are responsible for the hemolytic anemia.

Yu et al. (*12*) incubated human leukemia tumor cells in vitro with dCF and dAdo and found a marked rise in dATP and a decrease in ATP and GTP. One patient with T-cell leukemia was treated with dCF, and the concentrations of dATP, ATP, and GTP were monitored via HPLC in leukemia cells. Concentrations of dATP rose while those of ATP fell.

Siaw et al. (*6*) reported decreased erythrocyte ATP levels in a patient who developed hemolysis after treatment with dCF. This patient had a marked fall in erythrocyte ATP as well as an increase in dATP and inhibition of *S*-adenosyl-L-homocysteine hydrolase. The decrease in ATP occurred over 11 days; hemolysis was observed at about this time. Smith et al. (*7*) have reported that ATP levels fall in mouse erythrocytes after dCF treatment. Our results are consistent with their data in that we also observed a decrease in erythrocyte ATP after dCF.

An unexpected finding in our studies was the low ATP levels in animals that received both dCF and Ado; Siaw et al. (*6*) suggested that dCF might interfere with ATP generation. The decreases in ATP that we observed do not correlate with hemolysis, since mice given 1 mg dCF/kg and 400 mg/kg of either Ado or dAdo had profound falls in ATP levels without changes in hematocrit.

In contrast to our finding are the findings of Smith et al. (*7*) who reported that the ip injection of Ado in dCF-treated mice increased the occurrence of hemolysis. The explanation for this difference in toxicity between our two laboratories is unclear at present but may reflect differences in toxicity encountered by various clinical investigators (*2–6*). The important point is that massive transient hemolysis in mice has been documented by two laboratories.

Possible explanations for the massive hemolysis observed have been examined. First, dCF-induced changes in Ado and ATP metabolism might affect the erythrocyte membrane. These changes could lead to alterations in the surface properties of the cell, which are detectable by the spleen. The data presented above do not support this hypothesis, since splenectomized animals demonstrated hemolysis. In addition, careful examination of peripheral blood smears at hourly intervals from the time of drug injection until the onset of hemolysis revealed some spherocytes but very few burr cells or cell fragments.

Another possible explanation could be that high circulating levels of Ado or dAdo result in intracellular changes in the corresponding nucleotide since the nucleoside transport system of erythrocytes is very efficient (*13*). However, no hemolysis was observed when mice were infused with Ado or dAdo after pretreatment with dCF at a concentration just below that known to cause hemolysis when used alone (*see* table 2).

Our data support the hypothesis that a sensitive subpopulation of cells is destroyed by exposure to dCF and that it takes about 6 days for this cell population to be reestablished. We are presently examining old and young murine erythrocytes for their susceptibility to dCF-induced hemolysis.

Clinical trials have used doses of dCF ranging from 4 to 160 mg/m^2 either as an iv push or as an infusion. Initial reports of toxicity in clinical trials were limited to lymphopenia and elevated serum uric acid levels (*5*). As more patients have been treated with dCF, a wider range of toxicities has been reported, including massive hemolysis (*4*, *6*). Although toxicity seen in an animal may or may not occur in patients, the hemolysis observed in these preclinical investigations should alert the clinical investigator to the possibility that hemolysis may complicate treatment.

Carcinogen-Induced DNA Damage and Cellular Alterations in F344 Rat Colon Organ Cultures[1,2,3]

Nitin T. Telang[4,5] *and* **Gary M. Williams**[4,6,7]

ABSTRACT—Optimized culture conditions were used to achieve prolonged survival of colon mucosa from conventional inbred F344 strain rats. Up to 21 days in culture, a high percentage of explants had viable mucosa with intact crypt columns and maintained active replicative DNA synthesis in the proliferative zone of the crypts. An acute 4-hour in vitro exposure to 0.5 m*M* of the colon-selective carcinogens 1,2-dimethylhydrazine dihydrochloride (DMH) and *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) produced 26 and 78% suppressions of replicative DNA synthesis, respectively, whereas the same exposure to the liver carcinogen dimethylnitrosamine produced only a 5% suppression. The thymidine-labeling index of DMH-exposed cells was lower than that of control cells at 1 day and then increased above the control values 7–21 days later. MNNG exposure produced pronounced morphologic changes in the crypt columns. MNNG-exposed cultures that were transplanted into the mammary fat pads of syngeneic female rats produced hypercellular cysts different from those formed by nonexposed fragments. These findings indicate that the acute and persistent effects of colon carcinogens can be studied directly on the target tissue in organ culture.—JNCI 1982; 68:1015–1022.

Techniques for organ culture of rodent colon fragments (*1–6*) now permit maintenance of this tissue in a defined environment for a variety of studies. Such organ culture systems have been used to demonstrate the metabolism of carcinogens by the cultured mucosal epithelium by 1) the determination of the binding of metabolites to DNA or the production of metabolites (*7, 8*) as well as by 2) the examination of carcinogen-induced modulation in cell replication (*1*) and in DNA synthesis (*3, 9, 10*). Although in vitro malignant transformation in mouse mammary gland organ cultures (*11*) and in explant cultures of human pancreatic duct (*12*) has been documented, neoplastic alteration of colon mucosa by in vitro exposure to colon-selective carcinogens has not yet been demonstrated. In the present study, acute and persistent effects of the colon-selective procarcinogen DMH, the liver carcinogen DMN, and the direct-acting carcinogen MNNG, which also produces colon tumors, were examined in a rat colon organ culture system. Transplantation of exposured fragments into the mammary fat pad was used to evaluate the nature of the morphologic alterations in carcinogen-exposed organ cultures.

MATERIALS AND METHODS

Animals.—Eight- to 10-week-old conventional male inbred F344 rats were used in all the organ culture experiments. As a prerequisite for organ culture, the animals were maintained on an antibiotic treatment of 0.08 mg neomycin sulfate/day and 200 U Mycostatin/day in the drinking water for 3–4 days before culture (*5*). The animals were killed by CO_2 asphyxiation, and the descending colons were collected in sterile Hanks' buffered salt solution. The organ cultures were initiated within 0.5 hour of procuring the tissues.

Organ cultures.—The basic organ culture technique used was similar to that of Shamsuddin et al. (*4*), as previously described (*5*). Full-thickness tissue fragments were attached by their serosal side to Metricel GA-4 filters (0.8 μm pore size) and were cultured in 60-mm bacteriological petri plates (Falcon Plastics, Oxnard, Calif.) in 5 ml of WME (*13*). The medium was supplemented with 10% calf serum, 1 mU insulin/ml and 1 μM dexamethasone. The antibiotics Mycostatin (100 U/ml) and gentamicin (100 μg/ml) were also included in the complete WME. The organ cultures were maintained at 37°C in an atmosphere of 95% O_2:5% CO_2 and were rocked at 10 cycles/minute to achieve intermittent exposure of the tissue to the gas and liquid phases. Routinely, the culture medium was replenished every 24 hours during the 1st week and every 48 hours thereafter.

Biochemical studies.—The interaction of carcinogens with the mucosal epithelium was assessed in short-term organ cultures by examination of the modulation in replicative DNA synthesis. After a 24-hour preincubation, the cultures were exposed to 0.5 m*M* DMN (Eastman Kodak Co., Rochester, N.Y.), DMH (*sym*-dimethylhydrazine dihydrochloride; Aldrich Chemical Co., Milwaukee, Wisc.), or to MNNG (Sigma Chemical Co., St. Louis, Mo.) for 4 hours; this dose was the maximally effective sublethal dose of DMN and MNNG. These cultures together with parallel solvent-exposed controls were then incubated with 10 μCi [^{3}H]-

dThd/ml (45–50 Ci/mmol; New England Nuclear Corp., Boston, Mass.) for 18–20 hours to label all the cells that entered S-phase during this interval.

The mucosal cells from these cultures were dissociated from the underlying stromal tissue by incubation of the fragments in 0.25% Pronase (Calbiochem-Behring Corp., San Diego, Calif.) for 25–30 minutes at 37°C. The cells detached after gentle scraping with a rubber policeman were recovered by centrifugation of the medium (800–1,000 rpm/10 min). The resulting pellet was used for DNA extraction essentially according to the method of Marmur (*14*), with minor modifications that have been found effective for DNA isolation from mammary gland organ cultures (*15, 16*). The mucosal cells were resuspended in SSC and were lysed in the presence of 1% sodium dodecyl sulfate by alternate freezing and thawing. The resulting lysate was extracted once with chloroform–isoamyl alcohol (24:1), and the aqueous fraction was submitted to incubation with RNase (500 μg/ml for 1 hr at 37°C) and subsequently with Pronase (500 μg/ml for 1 hr at 37°C). After another extraction with chloroform–isoamyl alcohol and centrifugation, the DNA from the aqueous phase was precipiated by the addition of 2 volumes of cold ethanol. The precipitate was dissolved in SSC, and 100-μl aliquots of the sample were taken for the determination of DNA-bound dThd radioactivity. The DNA content of the sample was determined by measurement of the absorbance at 260 nm and also by the ethidium bromide fluorescence assay of Beers and Whitliff (*17*).

Morphologic studies.—The cellular effects of DMH, DMN, and MNNG were examined in the organ cultures after a 4-hour exposure to the carcinogens. These carcinogen-exposed cultures together with the solvent-exposed controls were maintained in WME. Two hours before the harvest at the designated times, the organ cultures were incubated with 10 μCi [^{3}H]dThd/ml and fixed in 10% buffered Formalin. The paraffin sections of the fragments were submitted to standard emulsion autoradiographic procedures (*5, 18*). Only the longitudinally sectioned, intact crypt columns that had at least two labeled nuclei with at least five grains per nucleus were included in [^{3}H]dThd LI determinations. These were then compared with nonexposed controls to determine carcinogen-induced proliferative alterations.

Transplantation studies.—For these experiments, the colon organ cultures from female rats were exposed to 0.5 m*M* MNNG for 4 hours and were maintained in culture for 7 days before transplantation into the mammary parenchyma-free fat pads of syngeneic recipients of the same sex. The technique used for surgical removal of the mammary parenchyma from the recipients was similar to that described by DeOme et al. (*19*), Haslam and Bern (*20*), and Richards and Nandi (*21*). The transplantation was done contralaterally such that a single recipient was implanted with an MNNG-exposed fragment and a fragment from the solvent-exposed control group. The recipient animals were maintained on normal diet and were killed 3 and 6 months after transplantation. The histologic nature of the cellular outgrowths was assessed from the histopathologic examination of the fat pads after being stained with H & E. The functional integrity of the outgrowths was determined by the presence of PAS-positive material.

RESULTS

Colon Organ Cultures

Consistent with the previous observations of Reiss and Williams (*5*), the culture conditions that supported prolonged survival of colon mucosa from the conventional mouse or the germfree rat were found to be equally conducive for maintenance of tissue from the conventional rat. Seventy-seven percent of fragments displayed intact crypt columns at 21 days in culture, and the surviving crypt columns showed persistent DNA synthesis in the crypts (table 1). During the initial phases of culture, the fragments frequently possessed shallow crypt columns, but in 14- and 21-day cultures, the surviving crypt columns were of normal height and had a normal cell number, thus resembling the day-1 cultures. The average number of cells ± SD per crypt column at days 1, 7, 14, and 21 were 37±4, 25±6, 36±5, and 39±3, respectively. The progressive increase in [^{3}H]dThd LI (table 1) was essentially similar to the increase reported by others (*6*).

Autoradiographic examination of explants pulsed with [^{3}H]dThd revealed that the mucosal cells in the lower third (normal proliferative zone) of the crypt column incorporated the radioisotope (figs. 1, 2). This pattern of labeling was consistently observed throughout the duration of culture.

In Vitro Effects of Carcinogens

The interaction of DMN, DMH, or MNNG with mucosal cell DNA was examined by evaluating the effect on DNA synthesis after an acute exposure of the cultures to the carcinogens. A 4-hour exposure to equimolar concentrations of the colon carcinogens DMN (activation-dependent) or MNNG (activation-independent) produced a 26–34% and a 74–78% suppression of incorporation of [^{3}H]dThd, respectively, in replicate experiments over the next 20 hours (table 2). In contrast, a similar exposure to the activation-dependent liver carcinogen DMN resulted in only a 5% suppression. The inhibition of replicative DNA synthesis by DMH but not by DMN is consistent with a selective ability of the colon mucosal epithelium to metabolize the colon carcinogen.

The differential susceptibility of mucosal cells to effects of DMN, DMH, and MNNG, as seen by the reduction in DNA-associated [^{3}H]dThd radioactivity (table 2), was also

TABLE 1.—*Condition of mucosal epithelium of rat colon in organ culture*

Culture duration, days[a]	Survival[b]	Average percent [^{3}H]dThd LI[c] ± SD
1	8/8 (100)	6.0±1.5
2	8/8 (100)	8.5±0.4
7	15/16 (94)	9.7±0.4
14	13/15 (87)	19.0±7
21	17/22 (77)	18.0±6

[a] Explant cultures were maintained in serum-supplemented WME. After requisite times, cultures were labeled with 10 μCi [^{3}H]dThd/ml for 2 hr before being harvested.

[b] No. of fragments with intact crypt columns open to the luminal surface/No. of fragments cultured (%).

[c] (No. of labeled cells/total No. of crypt cells) × 100, as determined in three separate experiments.

manifested as reduced [^{3}H]dThd LI ± SD immediately after carcinogen exposure. Thus the percent [^{3}H]dThd LI ± SD at 20 hours after DMH and MNNG exposure was found to be 6±2 and 3±1%, respectively. In contrast, DMN exposure did not result in any reduction, with the percent [^{3}H]dThd LI ± SD being 11±2%, which was comparable to the control value of 10±2%.

Continued maintenance of cultures exposed to DMH or MNNG resulted in a marked enhancement in the LI within 7 days, with the percent [^{3}H]dThd LI ± SD of 14±2 and 18±1%, respectively. The morphologic abnormalities in these cultures included shortening of the crypt columns, with DNA-synthesizing cells extending up the crypts into nonproliferative regions (figs. 3, 4). In contrast, DMN exposure did not produce any change in the [^{3}H]dThd LI or in the morphology of the crypt columns as compared to the LI or the morphology of the controls.

Examination of cultures exposed to DMH and MNNG and maintained for 14 or 21 days revealed significant morphologic changes in surviving crypt columns. Although DMH exposure induced progressive enhancement in the percent [^{3}H]dThd LI ± SD from 14±2% at 7 days to 30±4% at 21 days, this modulation in DNA synthetic activity was not accompanied by morphologic changes other than by shortened crypts. In contrast, MNNG exposure resulted in progessively increased atypical changes, such as shortened crypt columns, crypts showing hypercellularity, and epithelial cells showing loss of polarity (fig. 5). These crypts displayed increased mitotic activity (table 3).

TABLE 2.—*Effect of carcinogens on DNA synthesis in [^{3}H]dThd-labeled rat colon organ cultures*[a]

Carcinogen	Radioactivity in tissue homogenate					
	Experiment I			Experiment II		
	cpm/100 μl supernatant fraction[b]	cpm/μg DNA[c]	Inhibition, % of control	cpm/100 μl supernatant fraction[b]	cpm/μg DNA[c]	Inhibition, % of control
None	7,700	611	0	7,780	617	0
DMN	6,316	579	5	6,350	582	6
DMH	5,802	453	26	5,200	406	34
MNNG	2,627	138	78	2,770	145	74

[a] After an initial 24 hr preincubation, cultures were exposed to 0.5 m*M* DMN, DMH, or MNNG for 4 hr. Carcinogens were aspirated, and [^{3}H]dThd was added to the cultures for 18–20 hr. Mucosal epithelial cells were dissociated, and DNA was extracted as detailed in "Materials and Methods."

[b] Radioactivity was determined in the ethanol-precipitable supernatant fraction of the mucosal cell lysate which had been digested with RNase and Pronase.

[c] DNA content was quantitated from the OD at 260 nm and by the ethidium bromide fluorescence assay.

TABLE 3.—*Acute cellular effects of MNNG on rat colon mucosa in organ culture*[a]

Culture duration after carcinogen exposure, days	Incidence[b] of:			
	Atypical crypt columns[c]		Fragments with mitotic cells	
	DMSO	MNNG	DMSO	MNNG
1	0/8	7/8 (87)	0/8 (0)	0/8 (0)
7	0/16	14/16 (87)	0/16 (0)	4/16 (25)
14	0/24	16/18 (88)	3/24 (12)	7/18 (39)

[a] Explant cultures were exposed to 0.5 m*M* MNNG or to the solvent dimethyl sulfoxide (DMSO) for 4 hr and were subsequently maintained in serum-supplemented WME.

[b] Data for No. of cultures with characteristic/No. of cultures examined (%) were pooled from two separate experiments having a range of variation of <5%.

[c] These shallow crypts had DNA-synthesizing and dividing cells in the nonproliferative regions, and columns showed hypercellularity and loss of polarity.

TABLE 4.—*Fate of MNNG-exposed colon organ cultures transplanted into mammary fat pads*[a]

Treatment group	No. of fat pads examined	Fate of implants[b]		
		Resorbed	Persisting with single-layered epithelium	Persisting with hypercellular epithelium
DMSO, controls	14	8	6	0
MNNG-exposed	12	2	0	10

[a] After a 4-hr exposure to 0.5 m*M* MNNG or to the solvent dimethyl sulfoxide (DMSO), the cultures were maintained for 7 days in WME. Fragments were transplanted into inguinal mammary fat pads contralaterally.

[b] Grafts were recovered 3 mo after transplantation.

Transplantation Studies

Because only MNNG produced persistent atypical changes in mucosal crypts, to assess the nature of these cellular alterations we exposed cultures to MNNG and transplanted them into the parenchyma-free mammary fat pads of syngeneic female recipients. The extent of survival and the morphologic appearance of the colon mucosa from MNNG-exposed explants were compared to those of parallel controls that had been transplanted contralaterally into the same recipients. The MNNG-exposed transplants showed a higher incidence of survival than the controls (table 4). The control transplants that survived beyond 3 months in this heterotopic site formed hollow cysts that were lined by a single layer of columnar epithelium (fig. 6). In contrast, the cysts formed from MNNG-exposed implants had intact crypt columns as well as hyperplastic and dysplastic mucosal glands (figs. 7–9). Generally, the cysts formed by the control transplants were smaller in size than cysts from MNNG-exposed transplants. Functional integrity of the mucosal epithelium in both control and exposed explants was evident from the PAS-positive material, both on the cell surfaces and in the lumina of the cysts.

DISCUSSION

Prolonged in vitro maintenance of colon mucosa from conventional rats has been reported by several groups (*2, 4–6*). However, morphologic integrity of the mucosal epithelium in most of these cultures (*2, 4, 6*) was found to be drastically altered as early as 14 days after the initiation of cultures, and the mucosal epithelium was seen as a single layer of surface epithelium without any crypts. In contrast, Reiss and Williams (*5*) have reported a high incidence of intact crypt columns in colon organ cultures from conventional mice and germfree rats up to 35 days. Using descending colons from the conventional rat and the supportive culture conditions that were identified by Reiss and Williams (*5*), we achieved consistent long-term survival of intact crypt columns for a period of at least 21 days in the present study. Moreover, the pattern of DNA synthesis in these explant cultures was similar to that occurring in vivo (*22–26*). Thus the present results confirm our previous preliminary observations (*10*) in which the degree of preservation of the colon mucosal epithelium was compared in the cultures from the conventional mouse and rat. The preservation of intact crypt columns in the mucosal epithelium is an important prerequisite for experiments in which the effects of carcinogens on the pattern of DNA synthesis in crypt columns are to be examined. Thus the results on long-term survival of intact crypt columns (table 1) demonstrate that specific modifications in the experimental system, such as pretreatment of the animals with antibiotics, the use of Metricel filters as a substrate, and the presence of dexamethasone in an enriched culture medium, are useful for the long-term maintenance of morphologically normal colon mucosa.

The differential susceptibility of mucosal epithelium to in vitro carcinogen exposure was evident from the extent of suppression of [^{3}H]dThd incorporation into cellular DNA and also from the kinetics of increase in [^{3}H]dThd LI after carcinogen exposure. Thus the colon-selective, activation-dependent carcinogen DMH and the direct-acting agent MNNG produced greater suppression of [^{3}H]dThd incorporation than did the metabolism-dependent liver carcinogen DMN. Furthermore, the severity of suppression of DNA synthesis and its subsequent rebound was more pronounced after DMH exposure than after DMN exposure. The inhibition of replicative DNA synthesis produced by DMH and the subsequent time-dependent reversal of this inhibitory effect, as seen in the present study, are consistent with the response induced by DMH and a form of its metabolite, MAM acetate, in rabbit colon organ cultures (*3*). Carcinogen-selective inhibition of replicative DNA synthesis by DMH and by MAM acetate but not by benzo[*a*]pyrene has also been observed in explant cultures of human colon (*27*). An essentially similar inhibition in the level of replicative DNA synthesis in vivo was reported in the rat colon after a single intrarectal instillation of DMH (*28*) or after a single iv infusion of MAM acetate (*29*). In mouse colon, Chan et al. (*30*) found a rapid reduction in the number of DNA-synthesizing cells after exposure to DMH. These studies, which indicate an interaction of the carcinogens with DNA, are consistent with other in vivo studies in which DMH has been shown to form adducts in colon DNA (*31, 32*). Likewise, exposure of colon organ cultures to radiolabeled procarcinogen has resulted in the association of radioactivity with cellular DNA (*2, 10*) or in the formation of carcinogen–DNA adducts (*8*). These in vitro studies therefore are suggestive of an intrinsic carcinogen-metabolizing capacity of the colon with generation of DNA-damaging metabolites.

The increased DNA synthesis in crypts of carcinogen-exposed fragments maintained beyond the acute exposure has not been observed in other organ colon studies, although return toward normal levels of DNA synthesis has been reported (*3, 27*). The increase found in the present study is qualitatively similar to the increase found in in vivo studies (*28, 29*) and could represent either an expansion of the stem cell population or a loss of some of the upper differentiated, nonproliferative cell compartment in the shortened crypts, resulting in a greater relative number of the stem cells.

Induction of morphologic abnormalities in rat colon after repeated injections of AOM has been reported by Shamsuddin and Trump (*33*), with the predominant atypical lesion being mucous cell hyperplasia. In a subsequent report (*34*), these investigators examined the effect of in vitro exposure to MNNG of colon organ cultures from rats pre-exposed in vivo to four weekly doses of AOM. These investigators observed focal areas of hypercellularity, loss of polarity, and anaplasia at 1 and 2 weeks after MNNG exposure. The total time required for the morphologic expression of carcinogen-induced changes was about 10 weeks. In the present experiments, a single in vitro exposure to MNNG produced a molecular defect within 24 hours of carcinogen exposure, and the resulting morphologic lesions showed a time-dependent increase at 7 and 14 days of culture. The occurrence of morphologic changes in the crypts of cultures exposed to a single dose of MNNG and the time-dependent increase in the incidence of these morphologic lesions reflects a high degree of sensitivity of the present experimental system.

Inasmuch as an acute exposure to DMH (*35*), to its proximate metabolite MAM acetate (*36*), or to MNNG (*37*) has been shown to produce malignant conversion of colon epithelium, the inhibition of replicative DNA synthesis by a single exposure to DMH or to MNNG, the induction of persistent cell proliferation in nonproliferative regions of the crypt columns, and the production of atypical crypt columns after carcinogen exposure, as observed in the present experiments, are suggestive of a relevant alteration in the target tissue after in vitro exposure to the carcinogens.

The enhanced cellularity in MNNG-exposed transplants probably reflects the cellular expression of a carcinogen-induced molecular change which enables the mucosal epithelium to proliferate in a heterotopic site. Although transplants of rodent colon adenocarcinoma are known to exhibit progressive growth (*38–40*), normal colon mucosa, when transplanted, has shown only a limited growth potential. Thus Fergusson and Parrott (*41*) have demonstrated the survival of fetal mouse colon up to 2 months, whereas fragments of adult mouse small intestine were reported to survive for about 1 month (*42*). In a recent report, Valerio et al. (*43*) have described the survival of human xenografts of colon in nude mice. From among the various sites of transplantation that were tested, such as renal subcapsular, intrapertoneal, and subcutaneous, only the last-mentioned site supported the prolonged survival of colon transplants for about 3 months. The rat mammary fat pad as a site of transplantation has been used extensively for examination of malignant transformation in mammary tissue (*20, 21*). However, little evidence is available on the ability of mammary fat pads to support the growth of nonmammary tissue. Williams et al. (*44, 45*) and Jirtle et al. (*46*) have demonstrated that liver tissue can survive in this transplantation site. Consistent with all these observations, in the present study prolonged survival of colon fragments was obtained, and in addition, a difference in the nature of outgrowths from MNNG-exposed fragments, compared to the nature of the outgrowths from nonexposed fragments, indicates that mammary fat pad transplantation could be a useful assay system for analysis of the effects of carcinogens and promoters on colon cultures.

Cross-Resistance of Cultured Murine Leukemia Vincristine-Resistant P388 Cells to Vinblastine, Vindesine, and Bis(*N*-ethylidene vindesine) Disulfide, Disulfate[1,2,3]

Lee J. Wilkoff[4] *and* **Elizabeth A. Dulmadge**[4,5]

ABSTRACT—Cultured P388 leukemia cells derived from vincristine (VCR)-resistant cell populations developed in vivo in (C57BL × DBA/2)F_1 mice (P388/VCR) were cross-resistant to vinblastine (VLB), vindesine (VDS), and bis(*N*-ethylidene vindesine)disulfide, disulfate (bis-VDS). Cross-resistance was a function of concentration and time of exposure. Cultured P388/VCR cells were more sensitive to $6.1 \times 10^{-5}M$ bis-VDS than to $6.1 \times 10^{-5}M$ VDS or to $6.1 \times 10^{-5}M$ VLB. Cultured P388 cells derived from VCR-sensitive P388 leukemia passaged in vivo (P388/0) were significantly more sensitive to VDS and bis-VDS than to VLB. This degree of difference in sensitivity was also a function of concentration and time of exposure.—JNCI 1982; 68:1023–1026.

VDS and bis-VDS are synthetic vinca alkaloids that are derivatives of VLB (*1, 2*). These agents have been developed in an attempt to produce an effective chemotherapeutic agent with less neurotoxicity than that of VCR and with less hematologic toxicity than that of VLB (*1–3*). VDS has been reported to have pharmacokinetic properties different from those of VCR and VLB (*1, 4*). However, VDS and bis-VDS have similar molecular structures, bind to tubulin, and have a similar spectrum of responses in experimental animal tumor systems (*1, 2, 4, 5*).

VDS has been shown to be an active agent for treatment of childhood acute lymphocytic leukemia in relapse (*6*). However, the problem of the degree of cross-resistance between VCR and VDS has not been resolved (*3*). Although Mathé et al. (*7*) and Tan (*8*) have reported that patients considered to be resistant to VCR responded to treatment with VDS, Krivit et al. (*3*) presented evidence of clinical cross-resistance between VCR and VDS in patients with acute lymphocytic leukemia. Schabel et al. (*9*) showed that P388 tumors resistant to VCR (P388/VCR) were resistant to treatment with VCR and VDS and were partially resistant to VLB and bis-VDS. To determine if the target tumor cells of P388 murine tumors, independent of host factors, are resistant to VLB, VDS, and bis-VDS, we compared the sensitivity of cultured P388/VCR and P388/0 cells to the three agents. Preliminary results of these studies were recently reported (*10*).

MATERIALS AND METHODS

The P388/VCR tumor was developed by treatment of (C57BL × DBA/2)F_1 (BD2F_1) mice bearing the P388 ascites tumor with 1 mg VCR/kg body weight on days 1, 5, and 9 after ip implantation of 10^6 or 10^7 P388 cells as previously described (*11*). Proliferating cultured P388/0 cells were developed from sensitive cell populations passaged in vivo in BD2F_1 mice, and cultured P388/VCR cells were established from resistant cell populations developed after the 16th in vivo passage (*11*).

The P388/0 and P388/VCR cells were propagated in DMEM (*12*) supplemented with 10% horse serum and 2-mercaptoethanol (*13*) as previously described (*11*). Under these conditions the leukemia cell populations exponentially proliferated with doubling times (mean±SD) of 14.2±2.0 hours for P388/0 and 16.5±1.9 hours for P388/VCR between cell densities of 5.0×10^4 and 1.0×10^6 cells/ml. At the time of these studies, the P388/VCR cell line had completed approximately 1,600 doublings of the population in culture.

The effect of VLB, VDS, or bis-VDS on the viability of proliferating cell populations was determined by initiating cultures at a cell density of 10^5 cells/ml in a total volume of 100 ml medium in spinner flasks 48 hours prior to the addition of drug. The spinner cultures were incubated at 37°C on a magnetic stirrer. Proliferating cell populations were exposed to selected drug concentrations for 1, 2, 4, 6, or 24 hours, and the number of surviving cells was determined by colony formation in semisolid medium.

The semisolid medium used was DMEM supplemented with 20% horse serum, 50 μM 2-mercaptoethanol, 100 mg sodium pyruvate/liter of medium, and a final concentration of 0.15% agarose type II (Sigma Chemical Co., St. Louis, Mo.). Cells from the drug-treated P388 cultures were seeded at 10,000, 1,000, and 100 cells/tube in quadruplicate, and the cells from the control cultures were seeded at 100 cells/tube in a series of eight tubes. The tubes were incubated for 10–12 days in 5% CO_2 atmosphere. Only colonies with 50 or more cells were counted (*14*). Colony formation efficiencies of control cultures were 66±3.1% for P388/0 and 82.1±1.7% for P388/VCR.

VLB, VDS, and bis-VDS were dissolved in sterile, dis-

ABBREVIATIONS USED: bis-VDS=bis(*N*-ethylidene vindesine)disulfide, disulfate; DMEM=Dulbecco's modified Eagle's minimum essential medium; P388/0=P388 leukemia sensitive to vincristine; P388/VCR=P388 leukemia resistant to vincristine; TMC=theoretical maximum concentration(s); VCR=vincristine; VDS=vindesine; VLB=vinblastine.

Laster and Mrs. Mary Trader for providing the P388 leukemia and vincristine-resistant P388 tumors, and Mrs. Carol S. Eldridge for the excellent technical assistance.

tilled, and deionized water and diluted with cell culture medium to predetermined concentrations.

The sensitivities of cultured P388/VCR and P388/0 cell populations were compared by chi-square analysis. The standard errors of the ratios of surviving fractions of P388/VCR and P388/0 cell populations were calculated as described by Kendall and Stuart (*15*).

The in vitro concentrations of the agents used in this study can be compared with the estimated TMC that can be obtained in the body fluids of mice, with the assumption of rapid, equal distribution in all fluids following the administration of a drug dose lethal to 10% of the mice (*16*). The TMC for VLB is 8.0 μg/ml, for VDS 2.6 μg/ml, and for bis-VDS 2.0 μg/ml.

RESULTS AND DISCUSSION

When proliferating P388/0 cell populations were exposed to VLB, VDS, and bis-VDS for periods up to 6 hours, the results indicated that VDS was the most cytotoxic and VLB was the least cytotoxic of the three agents (table 1). For instance, there was no detectable decrease in viability of the cell populations exposed to 8.0 μg VLB/ml throughout 6 hours. However, P388/0 cell populations exposed to 2.0 μg bis-VDS/ml for 6 hours exhibited a 2.2 $\log_{10}$ reduction in viability, and when these populations were exposed to 2.6 μg VDS/ml for 6 hours, a 2.4 $\log_{10}$ reduction in viability was detected. When the exposure period was increased to 24 hours, a maximum degree in reduction of viability of the cell populations (3.7 $\log_{10}$ reduction in viability) was observed for all three agents at these concentrations.

Cultured P388/VCR cells treated with VLB, VDS, or bis-VDS exhibited cross-resistance to the vinca alkaloids (table 1). When the sensitivity of P388/VCR cells is compared with that of P388/0 cells to the three agents after a 24-hour exposure period, it is evident that the surviving fractions of the P388/VCR cells treated with VLB, VDS, or bis-VDS were significantly greater than the surviving fractions of the P388/0 cells treated with the same agents. Furthermore, when the sensitivities of P388/VCR and P388/0 cell populations are compared to VDS and bis-VDS as a function of time, it is apparent that at each time interval the surviving fractions of the P388/VCR cells treated with 0.26 or 2.6 μg VDS/ml or 2.0 μg bis-VDS/ml were significantly greater than the surviving fractions of the P388/0 cells.

In another series of experiments we compared the sensitivities of P388/VCR and P388/0 cells to equimolar concentrations of VLB, VDS, and bis-VDS after a 6-hour exposure period (table 2). Cross-resistance to VLB was demonstrated at concentrations of 6.1×10^{-6} and 6.1×10^{-5} *M* when the surviving fractions of the P388/VCR cell

[a] Proliferating cells were exposed to drugs, and the number of cells surviving drug treatment was estimated by assay in semisolid medium as described in "Materials and Methods."

[b] S_f=surviving fraction.

[c] Standard error of the ratio was estimated as described in (*15*).

[d] S_f's for each exposure period were compared with the use of chi-square analysis. NS=not significant.

populations were compared to the surviving fractions of the P388/0 cell populations. Cross-resistance to VDS and bis-VDS was detected at concentrations between 6.1×10^{-7} and 6.1×10^{-5} *M*. The data also indicate that cultured P388/VCR cells were more sensitive to 6.1×10^{-5} *M* bis-VDS than to 6.1×10^{-5} *M* VDS or VLB. In addition, we observed that at these equimolar concentrations, the P388/0 cell populations were significantly more sensitive to the VLB analogues than to VLB.

Cultured P388/VCR cell populations are not only cross-resistant to VLB, VDS, and bis-VDS (tables 1, 2) but also to adriamycin, adriamycin analogues (except cinerubin A), and actinomycin D (*11*), and are partially cross-resistant to VP16-213, a semisynthetic podophyllotoxin (*17*). Cultured P388/VCR cell populations were relatively sensitive to VP16-213 concentrations of 6.1×10^{-6} and 6.1×10^{-5} *M* (*17*). These VP16-213 concentrations (3.6 and 36.0 µg/ml) are physiologically attainable, since the TMC for VP16-213 is approximately 42 µg/ml (*17*). Although treatment of P388/VCR cell populations with 6.1×10^{-5} *M* (111 µg/ml) of bis-VDS for 6 hours resulted in a 1.2 $\log_{10}$ reduction in viability of the cell population, this concentration is relatively high since the TMC for this agent is 2.0 µg/ml (table 2).

Resistance and cross-resistance of cultured P388 cells to the vinca alkaloids was a function of concentration and time of exposure (table 1) (*11, 17*). Hill and Whelan (*18*) in a preliminary report indicated that cultured leukemia L5178Y cell populations resistant to VCR (L5178Y/VCR) are cross-resistant to VDS, and L5178Y cells resistant to VDS (L5178Y/VDS) are cross-resistant to VCR. They also reported that the presence or absence of cross-resistance appeared to be dose-dependent. Furthermore, they reported that both L5178Y/VCR and L5178Y/VDS cells were cross-resistant to VLB, adriamycin, and 4-epiadriamycin, and partially cross-resistant to actinomycin D.

Sweeney et al. (*19*) have reported that exposure of cultured Chinese hamster ovary cells to 2.8×10^{-8} *M* VDS, 8.3×10^{-8} *M* VLB, or 2.4×10^{-8} *M* VCR for 5 hours resulted in 40–50% accumulation of cells in mitosis. Although we did not determine accumulation of cells in mitosis, the results in table 2 indicate that 6.1×10^{-7} *M* VLB or VDS will produce 0.2 to 1.7 $\log_{10}$ reduction in viability of the P388/0 cell populations. We had previously reported that exposure of P388/0 cells to 6.1×10^{-8} or 6.1×10^{-7} *M* VCR for 6 hours would result in an 0.8 or 1.4 $\log_{10}$ reduction in viability of the P388/0 cell populations (*11*). The data reported by Sweeney et al. (*19*) with the use of 40–50% accumulation of mitotic cells as an end point, indicate that Chinese hamster ovary cells are less sensitive to VLB than to VDS or VCR (*19*). The data in table 2 and previously reported results with VCR (*11*), with the use of surviving cells in semisolid medium as an end point, indicate that P388/0 cells are also less sensitive to VLB than to VDS or VCR. Howard et al. (*20*) reported that the degree of mitotic arrest seen with the vinca alkaloids may depend on the cultured cell lines used. Their experiments with cultured leukemia L1210 cells showed that although VDS was the most effective agent in inhibiting cell proliferation and arresting cells in mitosis, VCR was less effective than VLB. Howard et al. (*20*) also reported evidence indicating that VDS had a greater effect than VLB or VCR on cyclic nucleotide metabolism in

L1210 cells.

Our observation of cross-resistance of cultured P388/VCR cells to VLB, VDS, and bis-VDS (tables 1, 2) is in agreement with the cross-resistance observed by Schabel et al. (*9*) for the in vivo passaged P388/VCR tumor, and indicates that cross-resistance is a function of the cellular properties of the P388/VCR cells and independent of any host factors. The cause of resistance and cross-resistance to the vinca alkaloids has not been defined. Reports have indicated that several factors may be involved, such as decreased drug transport across cell membranes (*21-24*), decreased drug retention by cells (*21, 24-29*), decreased binding affinities to target macromolecules (*24, 30*), altered intracellular distribution (*24, 25, 30*), and changes in cell membrane structure (*31, 32*). Because VLB and VDS are agents of clinical interest and because bis-VDS may have potential clinical utility, this cell culture system should provide an experimental model for investigation of the cause of resistance and cross-resistance to the vinca alkaloids.

Intracellular Adriamycin Levels and Cytotoxicity in Adriamycin-Sensitive and Adriamycin-Resistant P388 Mouse Leukemia Cells [1,2,3,4]

Ram Ganapathi, [5,6] **William Reiter,** [5,7] *and* **Awtar Krishan** [5]

ABSTRACT—Adriamycin (ADR) (NSC-123127) uptake and retention in ADR-sensitive P388 leukemia (P388/S) and ADR-resistant P388 leukemia (P388/R) cells were compared by fluorometry and laser flow cytometry (FCM) and were correlated with cytotoxic effects. Drug levels in P388/R cells treated in vitro with ADR (1–10 μg/ml) were twofold to fourfold lower than were levels in similarly treated P388/S cells. FCM analysis of P388/S and P388/R cells exposed in vitro to ADR showed qualitative and quantitative differences in ADR fluorescence profiles of drug-treated cells (1–5 μg/ml) but not of the isolated nuclei (0.5–10 μg/ml). Drug-induced perturbations in cell cycle traverse and chromosome aberrations were seen in P388/S but not in P388/R cells treated with 0.5–5 μg ADR/ml in vitro or 4–8 mg ADR/kg in vivo. The role of FCM in rapidly comparing and quantitating cellular ADR fluorescence profiles of ADR-sensitive and ADR-resistant tumors was demonstrated.—JNCI 1982; 68:1027–1032.

The rapid emergence of drug-resistant tumor clones continues to be a serious challenge in cancer chemotherapy. A number of biochemical and pharmacological studies have suggested that alterations in intracellular drug transport and retention, metabolic pathways, and target enzyme production may be responsible for drug resistance at the cellular level (*1–4*).

ADR and DAU are important anthracycline antibiotics with clinical activity against a wide variety of human cancers (*5, 6*). A number of recent studies on ADR- and DAU-resistant Ehrlich ascites (*7, 8*) and P388 mouse tumors (*9–11*) have suggested that anthracycline resistance is due to the reduced intracellular drug uptake and an enhanced drug efflux mechanism (*7, 8, 12, 13*).

Tumor cell populations are highly heterogeneous and contain subpopulations that differ in their response to the cytotoxic action of anthracyclines. Thus an assay system that will analyze drug uptake and retention in individual tumor cells (compared to conventional procedures for drug quantitation in cell homogenates) would be ideal for studying patterns of drug resistance at the cellular level. Some of our recent studies on detection and quantitation of cellular anthracycline content by direct laser excitation of individual cells have demonstrated the feasibility of this methodology for the study of anthracycline uptake and retention in tumor cell populations (*14*).

In the present study, we have compared intracellular ADR transport and retention by fluorometric and FCM methods in P388/S and resistant P388/R leukemia cells. We have also compared intracellular ADR levels with ADR-induced effects on cell cycle traverse, cytotoxicity, and induction of chromosome aberrations.

MATERIALS AND METHODS

P388/S and P388/R mouse leukemia cell lines (*9*) were obtained from Dr. Randall K. Johnson, Arthur D. Little, Inc., Cambridge, Mass. P388/S and P388/R tumor cells were maintained in female DBA/2 mice by weekly ip transplantation. Ascites from the ADR-sensitive and ADR-resistant tumors were also established as suspension cultures in RPMI-1640 tissue culture medium (Grand Island Biological Co., Grand Island, N.Y.) supplemented with 10% FCS (Flow Laboratories, Inc., McLean, Va.), 10 μm 2-mercaptoethanol, and the antibiotics penicillin and streptomycin.

Suspension cultures of P388/S and P388/R cells were exposed to ADR (0.1–5.0 μg/ml) for 24 hours, and cell counts were determined by trypan blue dye exclusion. Cultures treated with ADR (0.01–5.0 μg/ml) for 3 hours were centrifuged, washed twice in drug-free media, and plated (5×10^4 cells/plate) in 35×10-mm petri dishes with RPMI-1640 supplemented with 20% FCS, 10 μm 2-mercaptoethanol, and 0.3% agar. For continuous drug exposure, cells were plated with ADR (0.01–5.0 μg/ml) as above. After 8 days of incubation in a humidified 5% CO_2 atmosphere, colonies (>50 cells) in untreated control and ADR-treated plates were counted under an inverted tissue culture microscope. Plating efficiency of control P388/S and P388/R cells under these conditions was 16 and 4%, respectively.

P388/S and P388/R tumor cells (2×10^6/ml) from DBA/-2 donors were suspended in Eagle's minimum essential

medium supplemented with 10% FCS and incubated with ADR (1.0 and 10 µg/ml) at 37°C. Aliquots of 2×10^6 cells were removed at various times (30 min–4 hr), centrifuged, washed twice in 10 ml of cold 0.85% sodium chloride, and extracted with 50% ethanol–0.3 *N* hydrochloric acid and centrifuged (*15*). ADR fluorescence in the supernatant was determined at excitation and emission wavelengths of 470 and 585 nm, respectively, in an Aminco-Bowman Spectrophotofluorometer (American Instrument Co., Silver Spring, Md.). ADR content was computed from standard curves prepared with ADR hydrochloride (NSC-123127).

Female DBA/2 mice implanted with 10^6 P388/S and P388/R cells were treated ip on day 5 with 4 or 8 mg ADR/kg in 0.85% sodium chloride. Mice (2/group) were killed 1–4 hours after treatment, and intracellular ADR fluorescence was determined in duplicate P388/S and P388/R samples as outlined before.

In vitro cultures of ADR-sensitive and ADR-resistant tumor cells were incubated with 1.0 and 5 µg ADR/ml in RPMI-1640 supplemented with 10% FCS. Aliquots of cells after 1 and 3 hours of incubation were centrifuged at 80×*g* in a refrigerated centrifuge, resuspended in cold drug-free medium, and analyzed for intracellular ADR fluorescence by FCM (*14*). In this procedure, single cells in a sheath flow were excited by a monochromatic, 488-nm laser beam, and the light scatter or fluorescence emission was quantitated and scaled in a pulse-height analyzer. Intracellular ADR fluorescence was analyzed in a Coulter Electronics TPS-1 LL cell sorter (Coulter Electronics, Inc., Hialeah, Fla.) equipped with a Spectraphysics model 164-08 laser tuned to deliver 1.5 W at 488 nm. Data were collected on a TPS-1 data analysis module connected to a Hewlett-Packard 9845A desk-top computer. ADR-treated P388/S and P388/R cells (in vivo) were stained with propidium iodide–hypotonic citrate (*16*) and were analyzed for cell cycle distribution by FCM. Details of our procedures for laser excitation of intracellular ADR fluorescence, cell cycle analysis, standardization of instrumentation, and data analysis have been described (*14*).

Nuclear isolation was achieved by a 15-minute exposure of cells to 0.03% Nonidet P40 (Bethesda Research Laboratories, Inc., Gaithersburg, Md.) in Hanks' balanced salt solution. This procedure resulted in cell lysis and release of nuclei, which were washed twice and recovered by centrifugation at 200×*g*. Isolated nuclei were incubated at 37°C with ADR (0.5, 1.0, and 10 µg/ml). Nuclei were recovered by centrifugation, washed twice, and analyzed for ADR content by fluorimetry (after 50% ethanol–0.3 *N* hydrochloric acid extraction) and FCM.

For cytogenetic analysis, log-phase cultures (10^6 cells/ml) of P388/S and P388/R cells were treated with ADR (0.1, 1.0, and 5.0 µg/ml) for 6–8 hours. Then, 0.05 µg vinblastine sulfate (Eli Lilly & Co., Indianapolis, Ind.)/ml was added to the cultures for 2–4 hours before termination of the incubation. Cells were centrifuged and washed in Hanks' balanced salt solution, exposed to 0.075 *M* potassium chloride for 10 minutes at room temperature for hypotonic swelling, and then fixed in methanol–acetic acid (3:1 vol/vol) for 1 hour. Air-dried smears were stained with carbol fuchsin and analyzed for chromosome damage.

RESULTS

The effect of ADR on proliferation of P388/S and P388/R cells in suspension culture and as colonies in soft agar is shown in table 1. In suspension cultures of P388/R cells exposed to ADR (0.1–5.0 µg/ml) for 24 hours, no significant decrease in cell count (except at 5.0 µg/ml) was noted in contrast to markedly (drug concentration-dependent) reduced counts in P388/S cells. In the soft-agar assay, P388/S cells exposed to 0.01 µg ADR/ml for 3 hours (or continuously for 8 days) had only 8–10% (of control) colonies; however, P388/R had 100% (of control). No colonies were seen in P388/S cells exposed to higher concentrations of ADR (0.1–5.0 µg/ml) for 3 hours or continuously. In contrast, in P388/R cells exposed to 0.1 µg ADR/ml for 3 hours or continuously, the number of colonies counted were 88 and 64% of the control, respectively. Exposure of P388/R cells to 1.0 µg ADR/ml for 3 hours reduced the number of colonies to 18% of the control, whereas after exposure for 8 days (in soft agar), no colonies were seen. At a higher concentration of 5.0 µg ADR/ml, no colony growth was observed in P388/R treated for 3 hours or continuously. From these data, P388/R cells clearly demonstrated resistance to the cytotoxic effects of ADR in both the trypan blue dye exclusion procedure and the soft-agar colony-forming assay.

The uptake and intracellular retention of ADR (determined by fluorometric methods) by P388/S and P388/R cells treated in vitro with 1 and 10 µg ADR/ml are shown in text-figure 1. Differences in uptake were evident by the 1st hour of incubation and reached maximum values after 4 hours. Intracellular ADR levels in P388/S cells between 1 and 4 hours of incubation were twofold to fourfold higher than intracellular ADR levels in P388/R cells. In P388/S and P388/R cells treated in vivo with 4 and 8 mg ADR/kg, drug uptake and subsequent retention by P388/S cells were twofold to fourfold higher than were uptake and retention by similarly treated P388/R cells (table 2).

TABLE 1.—*Effect of ADR on growth and colony-forming ability of P388/S and P388/R cells*

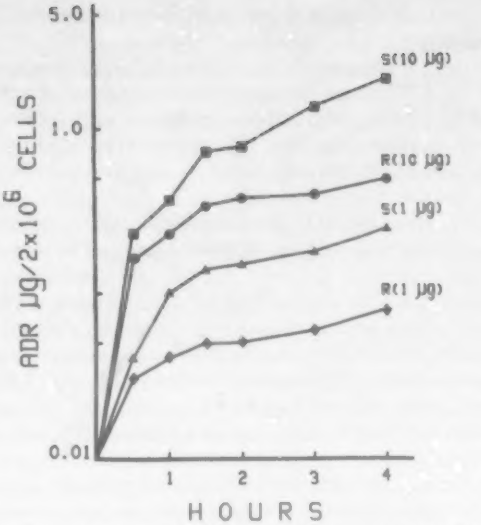
ADR concentration, µg/ml	Cell counts[a]		Colony assay[b]			
			P388/S		P388/R	
	P388/S[c]	P388/R	3 hr[d]	Continuously	3 hr	Continuously
0.01	—	—	10	8	100	100
0.1	38	118	2	0	88	64
1.0	13	98	0	0	18	0
5.0	0	50	0	0	0	0

[a] Cultures in triplicate were treated with ADR for 24 hr, and trypan blue dye-excluding cells were counted in a hemacytometer. —=not done.

[b] P388/S and P388/R cells were treated with ADR for 3 hr or continuously for 8 days and plated as outlined in "Materials and Methods."

[c] Number of dye-excluding cells in treated populations is expressed as a percentage of untreated controls.

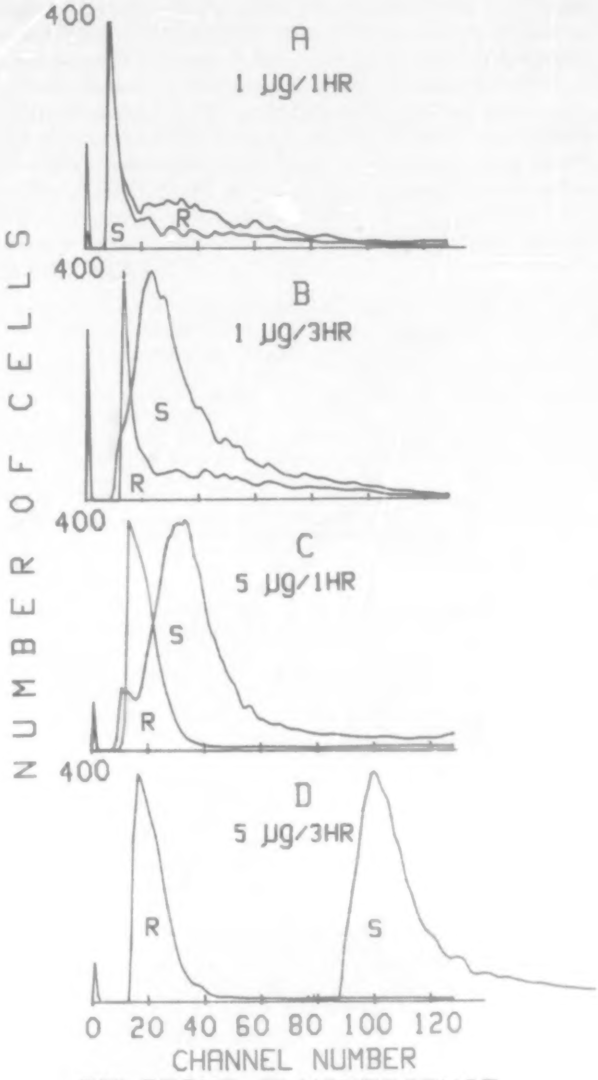
[d] Number of colonies (>50 cells) after 8 days of incubation is expressed as a percentage of control.



TEXT-FIGURE 1.—ADR uptake and retention profiles of P388/S (S; ▲, ■) and P388/R (R; ◆, ●) cells in vitro in the presence of 1 and 10 µg ADR/ml. Cellular ADR content was determined as outlined in "Materials and Methods." Each value represents the mean of three separate determinations; SD ≤10%.

Cellular drug fluorescence profiles of P388/S and P388/R cells incubated with ADR and analyzed by FCM are shown in text-figure 2. In cells treated with 1 µg ADR/ml and analyzed after 1 hour (text-fig. 2A), weak fluorescent signals could be detected in both P388/S and P388/R, and the peak of fluorescence distribution was at channel 15. In P388/S and P388/R cells, 72 and 18% of the population, respectively, could be detected (between channels 10 and 128) on the basis of their drug fluorescence. After 3 hours of incubation with 1 µg ADR/ml (text-fig. 2B), drug fluorescence in P388/S cells was twofold higher (fluorescent peak shifted from channel 15 to 30) than was fluorescence in P388/R (no major shift in fluorescent peak). In the drug-sensitive population, nearly 100% of the cells could be detected on the basis of ADR fluorescence as compared to only 25% of the cells in the drug-resistant subline.

Text-figure 2C shows the cellular drug fluorescence profiles of P388/S and P388/R cells treated with 5 µg ADR/ml for 1 hour. In both populations, approximately 80% of the cells could be detected by their fluorescence. However, in the ADR-sensitive population, cells were twofold more fluorescent (peak, channel 30) than cells in the ADR-resistant population (peak, channel 15). After 3 hours of incubation with 5 µg ADR/ml (text-fig. 2D), 100% of the P388/S cells could be detected by their fluorescence as compared to only 74% of similarly treated P388/R. Further, P388/S cells treated with ADR for 3 hours were threefold more fluorescent (peak, channel 100) than were P388/S cells treated with the same dose of ADR but for 1 hour (peak, channel 30). In contrast, P388/R cells treated with ADR for 3 hours



TEXT-FIGURE 2.—ADR fluorescence profiles of sensitive (S) and resistant (R) cells treated in vitro with 1 µg ADR/ml for 1 and 3 hr (A and B, respectively) and with 5 µg ADR/ml for 1 and 3 hr (C and D, respectively). Fluorescence amplification used was 50. Photomultiplier high-voltage setting was 500, and laser output at 488 nm was 0.75 W.

TABLE 2.—*ADR levels in P388/S and P388/R cells treated in vivo*[a]

Time, hr[b]	ADR concentration, $\mu g/5\times10^6$ cells, after mice were treated with:			
	4 mg ADR/kg body wt		8 mg ADR/kg body wt	
	P388/S	P388/R	P388/S	P388/R
1	0.61±0.03	0.32±0.10	1.55±0.02	0.37±0.03
2	0.67±0.10	0.18±0.02	0.99±0.05	0.27±0.01
4	0.44±0.06	0.23±0.06	0.79±0.05	0.3±0.01

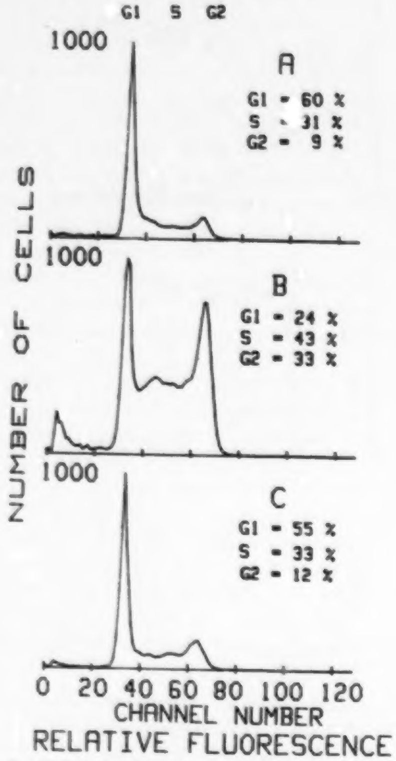
[a] Female DBA/2 mice were implanted ip with 1×10^6 P388/S or P388/R cells on day 0. On day 5, mice were treated ip with ADR in 0.85% sodium chloride.

[b] Tumor cells were retrieved at times indicated and analyzed as outlined in "Materials and Methods."

(peak, channel 20) showed only a marginal increase in the amount of cellular ADR fluorescence as compared to P388/R cells treated with the same dose of ADR but for 1 hour (peak, channel 15).

ADR-induced perturbations in cell cycle traverse were studied in P388/S and P388/R tumor cells from mice treated with 4 mg ADR/kg. As shown in text-figure 3, after 12 hours of drug treatment, accumulation of cells in the S-phase and G_2 phase was seen in P388/S (text-fig. 3B) but not in P388/R (text-fig. 3C) cells, for which the distribution was similar to that of an untreated control (text-fig. 3A).

In an earlier study (*17*), we reported that human lymphoblasts CCRF-CEM, human peripheral blood mononuclear cells, and P388 mouse leukemia cells exposed to ADR in vitro or in vivo and subsequently stained with the DNA-intercalating dye propidium iodide show a concentration and time-dependent reduction in fluorescence of the nuclear-propidium iodide complex. In the present study, P388/S and P388/R cells exposed to ADR in vivo (8 mg/kg) were subsequently stained with propidium iodide for cell cycle distribution analysis by FCM. In P388/S cells, a 15% reduction in the peak channel of propidium iodide nuclear fluorescence was seen after 4–8 hours, whereas P388/R cells showed no peak shift in the nuclear fluorescence.



Text-figure 3.—Cell cycle phase distributions of 12-hour, untreated control P388/S cells (A) and of ADR-treated (4 mg/kg) P388/S (B) and P388/R (C) cells 12 hr after treatment in vivo. DNA distribution histograms of 12-hr control P388/R cells were similar to the histogram 3A, except for an 8% decrease in the proportion of S-phase cells and a corresponding increase in cells with G_1 DNA content. Day 5 tumor-bearing mice were treated ip with drug, and retrieved tumor cells were analyzed by FCM after being stained with propidium iodide.

To test the hypothesis that intracellular ADR fluorescence between ADR-sensitive and ADR-resistant cells was related to differences in intracellular transport and retention and not to nuclear binding, we exposed isolated nuclei of P388/S and P388/R cells to 0.5, 1, and 10 μg ADR/ml and analyzed the ADR-treated nuclei by fluorimetry and FCM. No differences in ADR nuclear fluorescence were seen between P388/S and P388/R cells analyzed by either technique.

In P388/S cells exposed to 0.1 μg ADR/ml for 8 hours, mitotic plates were rare, and when present, they contained primarily fragmented and agglutinated chromosomes. Exposure to higher ADR concentrations (1.0 and 5.0 μg/ml) caused chromosomal agglutination and pulverization. In contrast in P388/R cells, concentrations of 0.1, 1.0, and 5.0 μg ADR/ml had no significant effect on mitotic index or chromosome morphology. Occasional mitotic plates containing agglutinated chromosomes were observed only at a dose of 5.0 μg ADR/ml.

DISCUSSION

Various mechanisms by which cells resist the cytotoxic effects of the anthracycline antibiotics DAU and ADR have been suggested (*3, 7, 8, 12, 13, 18, 19*). Studies on mouse tumor cells resistant to DAU and ADR have suggested specific mechanisms for drug resistance (*7, 8, 12, 13, 19*).

Fluorometric data from the present study show that intracellular uptake and retention of ADR were twofold to fourfold lower in the ADR-resistant cells than in the ADR-sensitive cells similarly treated. These results agree with those of earlier reported studies on ADR- and DAU-resistant mouse tumors (*7, 8, 12*). Comparison of drug uptake profiles (text-fig. 1) shows that, although intracellular ADR levels in P388/S and P388/R cells were similar after 30 minutes of incubation, on continued incubation, P388/S cells accumulated significantly more ADR than did P388/R cells. A 10-fold increase in extracellular ADR concentration resulted in an 8-fold increase in intracellular ADR levels in P388/S cells in contrast to a 5-fold intracellular increase of ADR by the P388/R population. Comparison of the in vivo ADR uptake profiles confirmed the in vitro differences in ADR uptake and retention by the P388/S and the P388/R cells. These results suggest that the salient difference between ADR-sensitive and ADR-resistant cells is the reduced ability of the ADR-resistant cells to transport and accumulate ADR.

Results from the FCM analysis of ADR fluorescence (text-fig. 2) in the P388/S and P388/R cells confirmed the in vitro fluorometric studies and further showed qualitative and quantitative differences in ADR uptake patterns between the two cell types. When P388/S cells were exposed to 1 and 5 μg ADR/ml, nearly every cell in the population was fluorescent after 3 hours, and the mean peak value of the fluorescence was much higher than that of P388/R cells similarly treated. In the P388/R population, the number of cells detectable was threefold higher in cultures exposed to 5 μg ADR/ml than in cultures treated with 1 μg ADR/ml, but the amount of cellular ADR fluorescence did not signif-

best copy available

icantly increase with the increase in ADR concentration. Unlike the ADR-sensitive population, the ADR-resistant cells showed no significant increase in the percentage of cells detectable by FCM with continued incubation (1 vs. 3 hr) with ADR. These results suggest that, in contrast to ADR-resistant cells, ADR transport and accumulation by the ADR-sensitive cells are more rapid and concentration-dependent.

Low intracellular ADR levels and possibly reduced ADR retention have been suggested as mechanisms for resistance to the cytotoxic effects of ADR (*7, 8, 12, 13*). Our studies by dye exclusion and soft-agar colony assay (table 1) indicate that P388/R cells are a hundredfold more resistant than P388/S cells to the cytotoxic effects of ADR. In a previous study (*12*), the basis of which was an in vivo bioassay, P388/R cells were shown to be 800-fold more resistant than were their ADR-sensitive counterparts. This quantitative discrepancy in resistance is probably due to the 1-hour drug exposure in the Inaba and Johnson study (*12*) in contrast to the 3-hour exposure in the present study. A number of other studies (*4, 14, 20*) and the one being reported here indicate that ADR is slowly transported across the cell membrane, and near steady-state levels of ADR are achieved in 2-4 hours. Our results indicate that on prolonged ADR exposure, cytotoxic ADR levels are also accumulated by P388/R cells and are expressed as decreases in colony-forming ability. Resistance to the cytotoxic effects of ADR in P388/R cells were further evident in the lack of ADR-induced cell cycle perturbations (text-fig. 3) and in chromosome damage. In contrast, P388/S cells showed the classical, concentration-dependent effect of ADR on cell cycle traverse, chromosome damage and cytotoxicity (*4, 21-23*).

Cytotoxic effects of ADR are suggested to occur after intercalation of the drug with DNA (*18, 24*). In the present study, fluorometric and FCM analyses of isolated nuclei from P388/S and P388/R cells incubated with ADR (0.5-10 µg/ml) showed no differences between the two cell types in the amount of nucleus-associated drug. Further, unlike the qualitative and quantitative differences seen in the cellular ADR fluorescence profiles of live cells (text-fig. 2) analyzed by FCM, no differences in nucleus-associated ADR were seen when ADR-treated isolated nuclei of P388/S and P388/R cells were analyzed. This result agrees with that of a study on the binding of DAU (0.05 and 0.1 µg/ml) to isolated nuclei of ADR-sensitive and ADR-resistant P388 cells (*12*). Reports on nuclear binding of DAU in DAU-sensitive and DAU-resistant Ehrlich ascites cells have been variable (*25, 26*). Dano (*25*) reported no significant difference in DAU binding in isolated nuclei of wild-type DAU-sensitive (near tetraploid) and in DAU-resistant (hyperdiploid) Ehrlich ascites tumor cells. Similarly, in comparing DAU binding in cell homogenates of DAU-sensitive and DAU-resistant Ehrlich ascites cells, Skovsgaard (*8*) found no differences at steady-state DAU concentrations at or below 1.0 µg/ml. Enhanced DAU binding in wild-type DAU-sensitive cells at higher steady-state DAU concentrations was suggested to be due to ploidy differences (*8*). In a recent study on DAU-sensitive and DAU-resistant Ehrlich ascites cells, Londos-Gagliardi et al. (*26*) using cell fractionation techniques reported nuclear-associated DAU levels in the DAU-resistant cells to be slightly lower than levels in the DAU-sensitive cells. However, when nuclear-DAU levels were expressed as a ratio of cellular DNA content, DAU levels in the DAU-resistant population were twofold to fourfold lower than levels in the DAU-sensitive cells. Possible reasons for this difference were not discussed, but differences in ploidy may be a plausible reason. In the present study, ploidy of P388/S and P388/R cells was similar, with a modal chromosome number of 40. Similarities in DNA content between the two cell types was further confirmed on analysis by FCM of propidium iodide-stained nuclei.

In conclusion, this study demonstrates that in P388/R cells cellular accumulation of ADR was twofold to fourfold lower than levels accumulated in P388/S cells. In the soft-agar colony assay, P388/R cells were a hundredfold more resistant to the cytotoxic effects of ADR than were P388/S cells. In contrast to P388/S, no dose-dependent effect of ADR on drug-induced cell cycle perturbations and chromosome damage was seen in P388/R. Resistance to ADR in P388/R was not due to reduced drug binding to the nucleus.

Thermotolerance in the Murine Jejunum [1, 2]

Kurt J. Henle [3, 4, 5]

ABSTRACT—The heat sensitivity of the murine jejunum from C3H/-HeJ mice and its capacity to develop thermotolerance were measured. Exteriorized loops of murine jejunum were heated in water baths at temperatures of 43-46°C for various times. Animal mortality was used to calculate the median lethal dose by day 7 ($LD_{50/7}$) in minutes as a function of temperature. The $LD_{50/7}$ value was independent of the length of the intestinal loop, the presence of serum in the heating medium, prior starvation of animals, and fluid replacement post heating. The time-temperature plot for the $LD_{50/7}$ values had an exponential slope constant of $-0.71°C^{-1}$, similar to that for other normal tissues. A heat treatment of 5 minutes at 45°C increased the $LD_{50/7}$ (total time at 45°C) from 5.9 minutes to 13.0 and 15.6 minutes for 1- and 3-day fractionation intervals, respectively. Death after intestinal heating was associated with septicemia and reached a peak on days 2 and 3 post hyperthermia. Gentamicin (0.1 mg/mouse/day) increased the $LD_{50/7}$ at 45°C from 5.9 to 9.6; however, septicemia was still noted in dying, gentamicin-treated mice. Additional antibiotics did not further increase the $LD_{50/7}$. Heat fractionation with gentamicin increased the $LD_{50/7}$ (total time at 45°C) to 23.0 and 12.5 minutes at 45°C for 1- and 3-day intervals, respectively. These data suggest that thermotolerance plays a significant role in the intestinal heat response, but that the heat damage to intestinal barriers against bacterial septicemia may be superimposed on the cellular damage to the crypt-villus system.—JNCI 1982; 68:1033–1036.

Hyperthermia is currently used on an experimental basis for the treatment of human cancers (*1*). Although the role of hyperthermia in the clinic is generally that of an adjuvant to either radiation or chemotherapy, more data are needed on the effects of hyperthermia alone in both normal and malignant tissues. In addition, the degree to which thermotolerance can be induced in various tissues must be known before the effects of fractionated hyperthermia can be assessed.

When compared to other normal tissues such as skin (*2*), the small intestine is one of the more radiation-sensitive tissues and also appears highly sensitive to hyperthermia. The purpose of this study was the quantitation of both the heat sensitivity of the murine small intestine and the development of thermotolerance in this tissue as indicated by animal lethality.

MATERIALS AND METHODS

Mice (C3H/HeJ) were purchased from The Jackson Laboratory, housed without special provisions, and used for experiments in a body weight range of 21–23 g at approximately 8 weeks of age. The mice were anesthetized ip with pentobarbital sodium (66 mg Nembutal/kg body wt; Abbott Laboratories), and a loop of jejunum (3.5 cm, unless otherwise noted) immediately distal to the ligament of Treitz was exteriorized through a 1-cm abdominal incision. The apex of this loop was marked with a loose suture through the mesenteric membrane and around the intestinal section. This suture was used both as the support for a 0.8-g weight that prevented flotation of the intestinal loop and as the identification of the same intestinal segment in the fractionation experiments. Neither the suture nor the weight appeared to constrict blood vessels. The exteriorized loops were covered with saline-saturated cotton gauze until 4 mice were prepared for simultaneous heat treatments (total preparation time: 10 min).

A picture of the experimental setup for heating the intestinal loops has been published previously in (*2*). A glass pan is covered by a plastic platform that contains four holes 1 cm in diameter. The glass pan is seated inside a 38-liter precision-controlled water bath (±0.05°C), and the heating medium for the intestinal loops is circulated by a pump through a stainless steel heat exchanger inside the bath and horizontally across the glass pan at a maximum flow rate of 3.4 liters/minute. The temperature gradients in the glass pan have been reported under these experimental conditions (*2*) and are insignificant at a depth of more than 2 mm below the air–fluid interphase. Since approximately 90% of the intestinal loop is more than 2 mm deep in the heating medium (maximum depth, 1.3 cm), heating is virtually uniform. The measured temperature transient in the intestinal lumen following immersion was equivalent to a lag time of 0.3 minute at 45°C, i.e., the difference between the total heating time and biologically equivalent time at constant temperature (*3*). Temperature gradients across the intestine were not detected in measurements under thermal equilibrium conditions (5 min after immersion). The temperature of the heating medium and rectal temperatures were monitored continuously (model 423; Yellow Springs Instrument Co.); core temperatures remained below 39.5°C at all times. Immediately before immersion of exteriorized intestinal loops, the temperature of the heating medium was raised 0.2°C above the target temperature to compensate for the cooling of the medium when the platform support was placed onto the glass pan.

Each experimental point on the graphs represents at least 8 animals with approximately equal numbers of males and

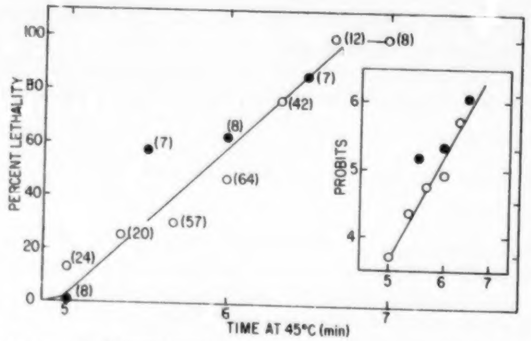
females. Both males and females showed a similar heat sensitivity (*see* SE of $LD_{50/7}$ in table 1), although a detailed study on the effect of animal sex on heat sensitivity was not performed. Survival data are analyzed by linear regression with the use of probits *(4)*.

RESULTS

Initial experiments were designed for identification of significant treatment variables for the heating of the exteriorized jejunal loops. In these experiments the $LD_{50/7}$ value at 45°C was determined with the use of: *a*) variable lengths of intestinal loop (3.5 vs. 6.5 cm); *b*) different heating media (McCoy's 5-A medium with and without 10% fetal bovine serum and Dulbecco's saline with and without penicillin-streptomycin antibiotics); *c*) varying intestinal content (24-hr prior starvation vs. free access to food until the experiment); and *d*) fluid replacement to counteract potential dehydration of the animal. [Ringer's saline (1 ml) was injected ip three times per day during the 3 days after the heat treatment. The fluid replacement eliminated the 7–8% weight loss that was normally observed.]

None of the above-listed variables had a statistically significant effect on the $LD_{50/7}$ at 45°C. Therefore, the results from all of these experiments were pooled in text-figure 1. An independent repeat experiment, with the use of the treatment conditions used for the remainder of the experiments (3.5-cm loop, Dulbecco's saline as heating medium, free access to food before heating, and no fluid replacement post heating), is shown separately by the solid symbols in text-figure 1. The inset of the graph shows the same data as probits versus natural logarithm of the heating time at 45°C; the calculated $LD_{50/7}$ value was 5.9 minutes (table 1).

The time of animal death after a single heat treatment peaked on the 2d day post heating, and more than 90% of the animals died within 5 days. Less than 3% of the animals died later than 7 days post heating. After fractionated hyperthermia, deaths peaked 1 day after the last treatment with no additional deaths after 4 days.



TEXT-FIGURE 1—Hyperthermia dose response for the exteriorized murine jejunum. Lethality within 7 days is plotted as a function of heating time at 45°C. The number of animals used for each datum is given *in parentheses*. *Inset* shows the same data when lethality is converted to probits and plotted against the natural logarithm of the heating time. ○, composite of several experiments with different heating media, fluid replacement after hyperthermia, and prior starvation (*see* text). ●, results of an independent repeat experiment; lines were fitted by eye; calculated values are given in table 1.

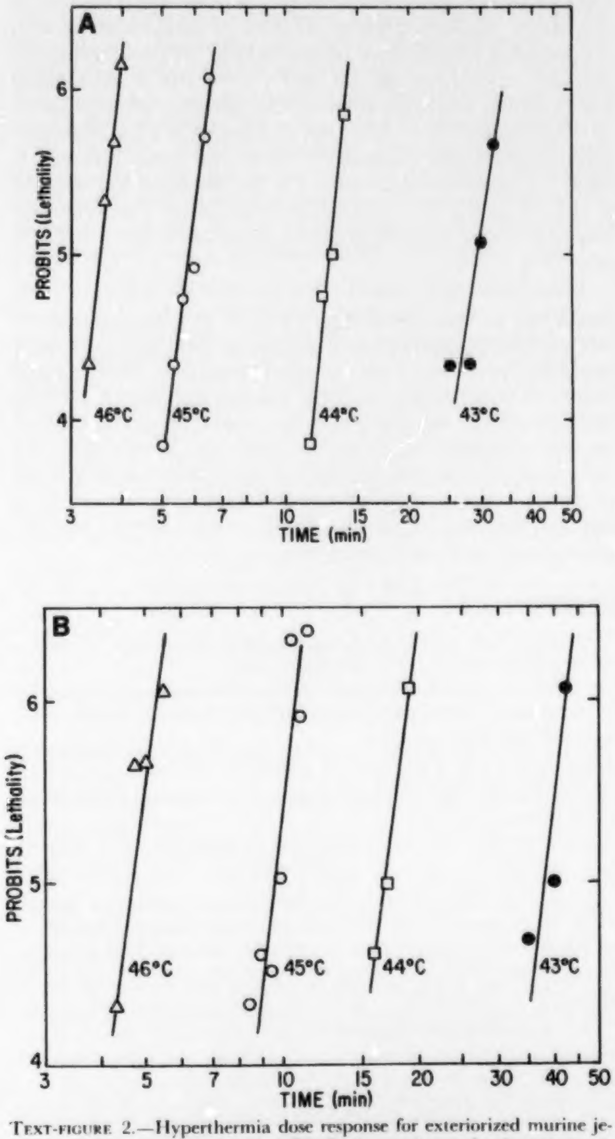
[a] Days after an initial treatment of 5 min at 45°C before reheating.
[b] Calculated values (min) of $LD_{50/7}$ and standard error of the mean with the use of *(4)*.

Cultures of cardiac blood from mice 2 days after lethal hyperthermia showed high levels of *Pseudomonas aeruginosa*. Gentamicin (0.1 mg/mouse/day) given ip (Garamycin; Schering Corp.) in two fractions daily during each of the first 3 days after hyperthermia increased the $LD_{50/7}$ at 45°C from 5.9 to 9.7 minutes (table 1, text-fig. 2). A similar increase in the $LD_{50/7}$ was measured in the temperature range of 43–46°C when mice were maintained on gentamicin. Lower temperatures were not included in this study since heating times in excess of 45 minutes required additional anesthesia. Cardiac blood cultures from mice on gentamicin 2 days after 10 minutes at 45°C to the jejunum showed the presence of *Moraxella*, but additional antibiotics (carbenicillin, ampicillin, and polymixin B) alone or in combination with gentamicin did not further increase the $LD_{50/7}$ at 45°C. The independent repeat experiment with gentamicin showed a reduced protective effect of the antibiotic (text-fig. 3) and blood cultures at this time detected the presence of some *P. aeruginosa*.

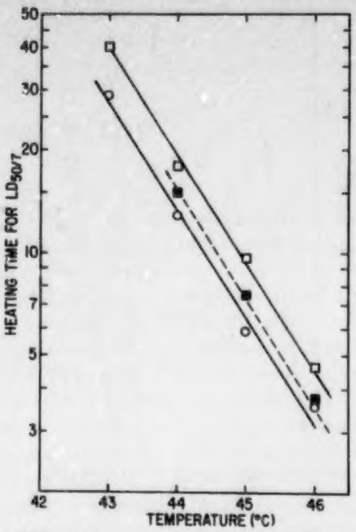
The increase in the $LD_{50/7}$ expressed as the total heating time with fractionated hyperthermia is shown in text-figure 4 with and without gentamicin. The intestinal loops were heated for 5 minutes at 45°C and reheated 0, 1, 3, or 5 days later with variable heating times at 45°C. (For the day-0 interval, 5 min at 45°C was followed by 3 min at 37°C before reheating.) Without gentamicin, the $LD_{50/7}$ increased from 5.9 to 13.0 and 15.6 at 45°C for the 1- and 3-day fractionation intervals, respectively (table 1, text-fig. 4A). Data for the 5-day fractionation interval are not shown since these experiments were complicated by the formation of intestinal adhesions. During exteriorization the breaking of these adhesions was accompanied by bleeding, and death after the second heat treatment could not be separated clearly from the effects of that mechanical trauma. Although the data for the 5-day fractionation interval had much scatter, the fractionation response resembled that of the 1-day fractionation interval.

Thermotolerance in the murine jejunum showed different kinetics in control and gentamicin-maintained mice. With gentamicin, the 1-day fractionation interval showed a higher level of thermotolerance than the 3-day interval, with $LD_{50/7}$ values of 23.0 and 12.5 minutes at 45°C, respectively (text-fig. 4B, table 1).

The temperature dependence of the $LD_{50/7}$ for single heat treatments with and without gentamicin is shown in text-figure 3. The time-temperature relationship shows a constant exponential slope with an average of $-0.71°C^{-1}$ without and with gentamicin, but with gentamicin the curve is shifted 0.2–0.5°C toward higher temperatures. Intestinal cross sections from non-gentamicin-treated mice 2 or 3 days after 6 minutes at 45°C showed no significant reduction in the number of regenerating crypts; however, gentamicin-maintained mice after intestinal hyperthermia of 9, 9.5, and 10 minutes at 45°C showed progressive but anisotropic destruction of crypts 2 days post heating. Crypt survival was not quantitated because of the nonuniform distribution of surviving crypts.



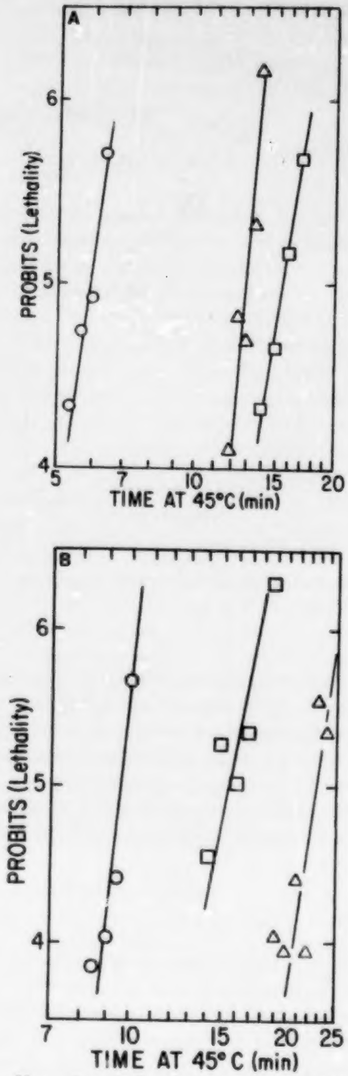
TEXT-FIGURE 2.—Hyperthermia dose response for exteriorized murine jejunum at temperatures of 43–46°C. Each experimental point represents 8–10 mice. The calculated $LD_{50/7}$ values are listed in table 1. A) Without gentamicin maintenance. B) With gentamicin maintenance over 3 days post hyperthermia (*see* text).



TEXT-FIGURE 3.—Time-temperature plot of the $LD_{50/7}$ with and without gentamicin. ○, data without gentamicin. □, data with gentamicin. ■, data of the independent gentamicin repeat experiment in which blood cultures revealed some *P. aeruginosa*.

DISCUSSION

The slope on the time-temperature curve in text-figure 3 is similar to that for other tissues (*2*). However, the heating time of the exteriorized jejunum required to kill 50% of the animals is only half of that required for 50% necrosis of rat skin and mouse ear, tail, or leg (*2*), even after gentamicin protection. Although it is difficult to compare heat sensitivity in different tissues when different experimental end points are used, the observations in this study suggest, nevertheless, that the small intestine is more heat-sensitive than skin. The measured $LD_{50/7}$ without gentamicin maintenance probably does not reflect cell killing of crypt stem cells, but rather the massive breakdown of barriers against bacterial invasion. Alternatively, the $LD_{50/7}$ with gentamicin maintenance appears to be associated with heat-induced killing of crypt stem cells. Crypt stem cell survival was not quantitated due to the asymmetry of surviving cells. Similar asymmetry was reported for intestinal sections treated with combined heat and radiation (*5, 6*). Higher crypt survival near the mesenteric side has been attributed to temperature gradients of the order of 1°C in the exteriorized intestinal loop, presumably due to cooling by circulating blood (*7*). In our system we could not measure any temperature gradients in the intestinal segments immersed 1 cm in the heating medium, and this result agrees with that in (*5*).



TEXT-FIGURE 4.—Hyperthermia fractionation response (45°C) of exteriorized murine jejunum. Jejunal segments were heated for 5 min at 45°C on day 0 and reheated 0 (○), 1 (△), or 3 days (□) after initial hyperthermia. The plotted heating time is the total time at 45°C in the two fractions. A) Without gentamicin maintenance. B) With gentamicin during the fractionation interval and for 3 days after the second fraction.

Furthermore, the rapid temperature transients upon immersion (*3*) suggest that large temperature gradients do not exist at thermal equilibrium. It appears more likely that hyperthermia causes multiple nutrient and pH gradients across the intestine. Such gradients may be aggravated by general anesthesia. Relevant physiologic data are not available.

When hyperthermia was applied to the same intestinal segment in two fractions, the total $LD_{50/7}$ was increased. This observation suggests that thermotolerance had developed in the jejunum after the initial heat treatment of 5 minutes at 45°C. However, the relative contributions to the increased $LD_{50/7}$ by thermotolerance, as defined in vitro (*8*), and by repair of heat damage are unknown. Therefore, we cannot compare the magnitude of thermotolerance in vivo with that of thermotolerance in vitro, where tolerance is defined in terms of the ratio of slopes on hyperthermia survival curves (*8*). Furthermore, if thermotolerance in vivo is expressed in terms of a ratio of LD_{50} values, the magnitude of the ratio depends on the specific formulation of the ratio (*9*). However, the time course of thermotolerance is independent of the definition of a thermotolerance ratio. With the use of the simplest form of a thermotolerance ratio (i.e., total $LD_{50/7}$ fractionated/$LD_{50/7}$ single heating), the data in this study indicate different kinetics of thermotolerance in the presence and absence of gentamicin. Without gentamicin, this ratio becomes 2.2 and 2.7 for the 1- and 3-day fractionation intervals, respectively, whereas with gentamicin maintenance the ratio rises to 2.4 with a 1-day fractionation interval and declines to 1.3 for the 3-day interval. A peak in thermotolerance with a 1-day fractionation interval is similar to the thermotolerance kinetics in vitro (*8*) and resembles those kinetics observed in mouse feet (*9, 10*) and skin (*11*).

Thermotolerance kinetics for the murine jejunum with gentamicin may, therefore, reflect a cellular survival response, whereas without gentamicin the fractionation results could be based on an altered physiology that would retard bacterial invasion into the heat-traumatized jejunal section. Detailed histologic studies of the jejunal heat response to support this conjecture are not available. In any case, the data for mice without gentamicin show that measurements of heat sensitivity and thermotolerance in vivo include features that may be separate from, and not predictable by, in vitro cell survival experiments.

Detection of Acquired Provirus Sequences in Mammary Tumors From Low-Expressor, Low-Risk Mice[1,2,3]

Bruce W. Altrock,[4,5] **Robert D. Cardiff,**[4,6] **John P. Puma,**[4] *and* **Judi K. Lund**[4]

ABSTRACT—Murine mammary tumor virus (MuMTV) provirus sequences in the DNA from early-occurring (average age 10 mo) and late occurring (age >20 mo) tumors in BALB/cfC3H mice were analyzed by Eco RI restriction endonuclease mapping procedures. All early tumors were MuMTV antigen-positive mammary adenocarcinomas that contained the 0.92- and 4.0-kilo base (kb) exogenous C3H MuMTV-specific Pst I restriction endonuclease fragments. All but 1 of the late mammary adenocarcinomas had MuMTV antigens detected by peroxidase antiperoxidase staining, and all contained the 0.92- and 4.0-kb exogenous virus Pst I fragments. Three late nonmammary tumors lacked both MuMTV antigens and acquired provirus sequences. Greater numbers of MuMTV sequences were detected in both early and late-arising mammary tumors by Eco RI restriction endonuclease mapping than were detected in tissues from uninfected BALB/c mice. However, neither the number nor the location of MuMTV proviruses correlated with tumor latent period.—JNCI 1982; 68:1037–1041.

Exogenous MuMTV are highly oncogenic for the mammary epithelium of susceptible strains of mice and generally produce tumors with a mean latent period of 12 months or less (*1–4*). The presence of exogenous C3H MuMTV provirus sequences in BALB/cfC3H tumor tissue has been confirmed by the detection of exogenous MuMTV-specific 0.92- and 4.0-kb Pst I restriction endonuclease fragments by Southern blot analysis (*5*). However, the presence of exogenous MuMTV was not sufficient for neoplastic transformation to occur, since the same provirus sequences were detected in the normal lactating BALB/cfC3H mammary glands of infected females (*5*). Endogenous forms of MuMTV have also been detected in normal and neoplastic tissue of all inbred strains of mice (*6*). These endogenous proviruses apparently lack the highly oncogenic character of the exogenous MuMTV and can be distinguished from exogenous MuMTV proviruses by their restriction endonuclease maps (*5–7*). Endogenous MuMTV have been associated with mammary tumors that occur late in life (*8*). To date, exogenous MuMTV has not been associated with tumors occurring after prolonged latent periods (≥18 mo).

Recently, we have reported studies of tumor risk and latency in exogenously infected BALB/cfC3H mice (*1*). Two subpopulations of MuMTV-infected mice were identified in those studies; one group developed 100% tumors by 17 months of age with a mean age of detection of 10 months (high risk), whereas the other group did not develop tumors earlier than 20.5 months of age and exhibited only a 15% tumor incidence at 24 months (low risk). Although both groups expressed MuMTV antigens in their milk, the levels in the milk of high-risk mice were at least 33 times higher than those observed in the milk of low-risk mice. On the basis of the data available at that time, it was not known whether the tumors arising in both high-risk and low-risk mice possessed exogenous MuMTV sequences. The possibility existed that the tumors occurring in the low-risk BALB/cfC3H mice may have involved only endogenous MuMTV provirus information.

In the present studies we compared the morphology, virus antigenicity, and the MuMTV provirus sequences associated with mammary tumors arising in high-risk and low-risk BALB/cfC3H mice. Tumors observed in both groups were predominantly adenocarcinomas and contained viral antigens. Adenocarcinomas from high-risk and low-risk mice contained both exogenous and endogenous MuMTV provirus sequences and had comparable numbers of MuMTV provirus copies. Therefore, the acquisition of exogenous MuMTV proviruses may have been necessary, but was not sufficient, to ensure early tumor development.

MATERIALS AND METHODS

Mice and virus.—BALB/c and BALB/cfC3H mice were from Simonsen Laboratories, Gilroy, Calif. MuMTV virus from the Mm5mt/cl cell line was obtained from NCI-Frederick Cancer Research Facility, Frederick, Md., through the Biological Carcinogenesis Branch, National Cancer Institute.

PAP staining.—Paraffin-embedded tissues were sectioned at 5 μm, mounted on glass slides, and incubated at 56°C overnight. After dewaxing, we immersed the sections in absolute methanol containing 0.3% H_2O_2 for 3 minutes. After washing in 0.01 *M* PBS (pH 7.4), the sections were incubated with nonimmune goat serum diluted 1:10 for 30 minutes. Subsequently, we applied the following antisera sequence: rabbit anti-MuMTV, 1:500; goat anti-rabbit, 1:40; and rabbit PAP, 1:50. Each step lasted 30 minutes and was followed by a wash in PBS. The immune complex was detected with 3-amino-9-carbazole. We counterstained

the sections in Mayer's hematoxylin and mounted with Kaiser's glycerol gelatin (*9, 10*). Two investigators (R.D.C. and J.K.L.) viewed one or two PAP-stained sections of each tumor independently and recorded the percentage of MuMTV antigen-positive cells.

Nucleic acid extraction.—Tissues were minced, suspended in extraction buffer [10 m*M* Tris-HCl (pH 8.0), 10 m*M* NaCl, 10 m*M* EDTA], and disrupted with a dounce homogenizer. The homogenate was passed through cheesecloth. Proteinase K (500 μg/ml) and SDS (0.5%) were added to the filtrate. We incubated the mixtures at 43°C overnight and then extracted them twice with equal volumes of buffer-saturated phenol (*11*). The extracts were dialyzed exhaustively against 5 m*M* Tris-HCl (pH 8.0), 10 m*M* NaCl, and 0.1 m*M* EDTA.

Viral RNA was obtained by phenol extraction of SDS-disrupted proteinase K-digested virus. The RNA was disaggregated into 35S subunits by being heated at 90°C for 3 minutes and then by centrifugation in a 5–20% sucrose gradient. Material that sedimented at 20–35S was pooled, precipitated with ethanol, and dissolved in 10 m*M* Tris-HCl (pH 8.0), 50 m*M* KCl, and 1 m*M* EDTA.

Preparation of MuMTV [^{32}P]cDNA.—MuMTV-specific [^{32}P]cDNA was prepared in a 50-μl reaction mixture that contained 50 m*M* Tris-HCl (pH 8.1), 75 m*M* KCl, 10 m*M* MgCl$_2$, 2 m*M* DTT, 0.2 m*M* of each dGTP, dCTP, and dTTP, 100–200 μCi [α-^{32}P]dATP (2,000 Ci/mmol; New England Nuclear Corp. Boston, Mass.), 25 μg actinomycin D/ml, 0.5 μg MuMTV 20–35S RNA, 500 μg calf DNA primers (*12*), and 50 U of avian myeloblastosis virus reverse transcriptase (provided by Dr. J. Beard, Life Sciences Inc., St. Petersburg, Fla., through the Biological Carcinogenesis Branch, National Cancer Institute). The mixture was incubated at 37°C for 30 minutes. The reaction was stopped by the addition of EDTA, SDS, and NaOH to final concentrations of 50 m*M*, 0.5% and 0.3 *M*, respectively. The mixture was incubated at 65°C for 3–4 hours to hydrolyze the viral RNA, then neutralized with HCl, and passed over a column of Sephadex G-50. The [^{32}P]cDNA eluted in the void volume and was precipitated with ethanol and dissolved in 5 m*M* Tris-HCl (pH 8.0), 10 m*M* NaCl, and 0.1 m*M* EDTA.

Enzyme digests and blotting—Restriction endonucleases were purchased from New England BioLabs, Beverly, Mass. Digestion mixtures contained 5–20 μg cellular DNA and 1 μg λ-DNA in a solution of 50 m*M* Tris-HCl (pH 7.4), 50 m*M* NaCl, 5 m*M* MgCl$_2$, 5 m*M* DTT, and 50 μg lysozyme/ml. The reactions were incubated at 37°C and stopped by addition of EDTA, and the reaction products were electrophoresed in 1% agarose gels. We stained the gels with ethidium bromide and verified the completeness of digestion by the λ-DNA pattern. The transfer of DNA fragments from the agarose gels to nitrocellulose filters (Schleicher & Schuell, Inc. Keene, N.H.) was done as described by Southern (*13*). The filters were baked at 80°C in vacuo for 2–4 hours and then prehybridized for 6–18 hours at 37°C in annealing mix containing 3× SSC (0.45 *M* NaCl, 0.045 *M* sodium citrate), 40% (vol/vol) deionized formamide, 200 μg yeast RNA/ml, 50 μg sheared calf thymus DNA/ml, 1 m*M* EDTA, and 3× Denhardt's buffer (0.6% each of bovine serum albumin, polyvinyl pyrrolidone, and Ficoll) (*14*). Hybridizations were performed by incubating the filters (250 cm^2) with 2×10^6 cpm [^{32}P]cDNA in 2 ml annealing mix at 37°C for 4 days. Unhybridized cDNA was removed from the filters by being washed three or four times in 200-ml changes of buffer (2× SSC, 0.1% SDS, 5 ml saturated sodium pyrophosphate/liter) at 23°C, by being washed once in buffer for 0.5–1 hour at 65°C, and then by being washed once in 0.1× buffer at room temperature. The filters were air dried and then exposed at −70°C for 1–14 days to Kodak X-R5 X-OMAT film in the presence of Dupont Cronex intensifying screens.

RESULTS

Tumor morphology and antigenicity.—Tumors arising in high-expressor, high-risk mice (mean latent period, 10 mo) were all identified as adenocarcinomas according to the classification of Dunn (*15*) and contained MuMTV antigens detectable by PAP staining (table 1). By comparison 9 of 12 (75%) tumors arising in old (≥20.5 mo) low-expressor, low-risk mice were adenocarcinomas. All but 1 of the adenocarcinomas from low-risk mice had detectable MuMTV antigens. The level and distribution of detectable virus antigen were similar in tumors from high- and low-risk mice. The 3 nonmammary tumors from low-risk mice lacked detectable MuMTV antigens.

Pst I restriction endonuclease mapping.—The DNA extracted from tumors of 18 high- and low-expressor mice were digested with the Pst I restriction endonuclease and analyzed by the Southern blotting procedure with the use of [^{32}P]-labeled C3H MuMTV cDNA (fig. 1) (*14, 16*). The DNA from all tumors of high-expressor mice contained the 0.92- and 4.0-kb Pst I restriction endonuclease fragments characteristic of exogenous C3H MuMTV as well as the 0.77-, 1.4-, 1.7-, 4.8-, and 5.1-kb fragments of the endogenous BALB/c proviruses. The DNA from most mammary tumors of low-expressor mice also contained these exogenous and endogenous MuMTV Pst I fragments. One exception to this observation was the Pst I map of a late-arising (28 mo of age) MuMTV antigen-negative, low-expressor tumor ZII (table 1), which lacked the 4.8-kb endogenous provirus fragment. The DNA from the 3 nonmammary tumors from low-expressor mice contained only the endogenous BALB/c MuMTV provirus fragments.

Eco RI restriction endonuclease mapping.—Because Pst I maps of tumor DNA from high- and low-expressor mice were the same, we investigated next the possible differences in provirus numbers and sites of integration in low- and high-expressor tumors with the use of Eco RI restriction endonuclease (fig. 2). This enzyme cuts each MuMTV provirus once producing 4.0- and 6.1-kb MuMTV fragments coupled to their adjacent host cellular sequences (*17*). In BALB/c mouse spleen DNA, 5 Eco RI bands of 6.2, 7.2, 7.7, 9.2, and 15.0 kb were detected and represented endogenous MuMTV provirus sequences (*8*). Tumor cells that were infected with exogenous MuMTV acquired additional integrated provirus sequences, which could be detected as additional bands in Eco RI maps of cellular DNA (*5*). Tumors from high-expressor BALB/cfC3H mice evaluated by this procedure had from one to six additional Eco RI bands. This finding was consistent with the acquisition of exogenous MuMTV

TABLE 1.—*PAP and restriction endonuclease mapping data for high- and low-expressor BALB/cfC3H mice*

Animal No.[a, b]	Tumor type	PAP staining[c]	Exogenous MuMTV Pst I fragments, 0.92 and 4.0 kb	Additional MuMTV[d] Eco RI, fragments

3373	Lymphoma	−	−	0

[a] Tumors 87A and 87B were from the same animal.

[b] Tumor from animal #ZII lacked the 7.2-kb endogenous MuMTV fragment.

[c] PAP grading system: ± = 0–1% positive cells, + = 1–25% positive cells, ++ = 25–50% positive cells, and +++ = 50–100% positive cells.

[d] The 6.2-, 7.2-, 7.7-, 9.2-, and 15.0-kb endogenous MuMTV fragments are not included. The 0.92- and 4.0-kb endogenous MuMTV Pst I fragments are included for low-expressor mice.

proviruses reported to occur in these animals (*5*). In general, high- and low-expressor mammary tumors contained equivalent numbers of integrated MuMTV proviruses. All of the mammary tumors from low-expressor mice had from 1 to 6 additional Eco RI MuMTV fragments. All but animal ZII also had the expected endogenous provirus fragments. The ZII tumor DNA lacked the 7.2-kb endogenous fragment normally detected in BALB/c DNA. The nonmammary tumors from low-expressor animals that lacked MuMTV antigens and the 0.92- and 4.0-kb Pst I exogenous MuMTV fragment also lacked additional Eco RI fragments.

DISCUSSION

Most female BALB/c mice infected with C3H MuMTV by foster nursing or by injection develop mammary tumors early in life (mean latent period, 10 mo) (*1-4*). However, some exposed individuals do not develop tumors before 20 months of age, if at all. Our early studies demonstrated a relationship between the levels of milk MuMTV antigen expression in individual females and their respective tumor latent periods (*1*). Females with large amounts of milk MuMTV antigens (≥100 μg/ml; high expressors) developed early tumors, whereas those with low milk MuMTV levels (≤3 μg/ml; low expressors) either did not develop tumors or developed them late in life (15% by 24 mo of age). Although the milk from unexposed BALB/c animals did not contain detectable MuMTV antigens, we could not exclude the possibility that the antigen detected in low-expressor milk was from a derepressed, endogenous MuMTV provirus. Such endogenous MuMTV expression may also have played a role in tumor development in these animals (*8*).

We compared the morphologic and viral antigenic features of tumors from both high- and low-expressor mice. Mammary adenocarcinomas that arose in both high- and low-expressor mice (with one exception) were MuMTV antigen-positive. Though some nonmammary tumors did arise in the low-expressor population, these lacked PAP-detectable MuMTV antigens. Therefore, the morphologic and antigenic criteria used did not distinguish between high- and low-expressor mammary tumors.

Next we examined these tumors for the presence of exogenous MuMTV-specific Pst I restriction endonuclease fragments. All of the mammary adenocarcinomas found in high- and low-expressor females contained the Pst I 0.92- and 4.0-kb fragments characteristic of exogenous C3H MuMTV provirus (*5*). These fragments have not been observed in the liver, lactating mammary gland, hyperplastic outgrowths or tumors from our BALB/c colony. Therefore, we interpret their presence to indicate infection of the tissue by exogenous MuMTV (*5, 19*). The 3 MuMTV antigen-negative nonmammary tumors from low-expressor mice contained endogenous BALB/c MuMTV provirus DNA but lacked the 0.92- and 4.0-kb exogenous provirus fragments. These data indicate that the late-arising mammary adenocarcinomas from low-expressor mice were infected with exogenous MuMTV and expressed viral antigens in a manner comparable to that of high-expressor tumors.

We next compared the number and location of MuMTV sequences in tumors from both MuMTV expression groups. Mammary tumors from both high and low expressors contained additional copies of MuMTV genes as detected by Eco RI restriction endonuclease mapping. The numbers of additional MuMTV Eco RI fragments varied from one to six among the individual tumors tested. However, the number of additional fragments did not correlate with tumor latency. No C3H MuMTV host Eco RI fragments were detected, which were common throughout the high- or low-expressor mammary tumors studied. A unique situation was observed in the MuMTV antigen-negative mammary adenocarcinoma (animal #ZII) which contained the 0.92- and 4.0-kb exogenous MuMTV Pst I fragments and had six additional MuMTV Eco RI fragments but lacked one of the endogenous BALB/c MuMTV Eco RI fragments. Understanding the mechanism of this genetic rearrangement and its consequences will require further study.

The increased numbers of MuMTV provirus sequences detected in both low- and high-expressor mammary tumors is consistent with MuMTV involvement in tumor development in both groups of mice. However, no evidence of a correlation between MuMTV copy number or location and latent period (expressor status) was obtained. Although these studies exclude the hypothesis that the MuMTV found in low-expressor mice was exclusively endogenous virus, they do not provide a clear explanation for the prolonged latent period and low tumor incidence in low-expressor animals. Explanation of these concurrent phenomena awaits further study.

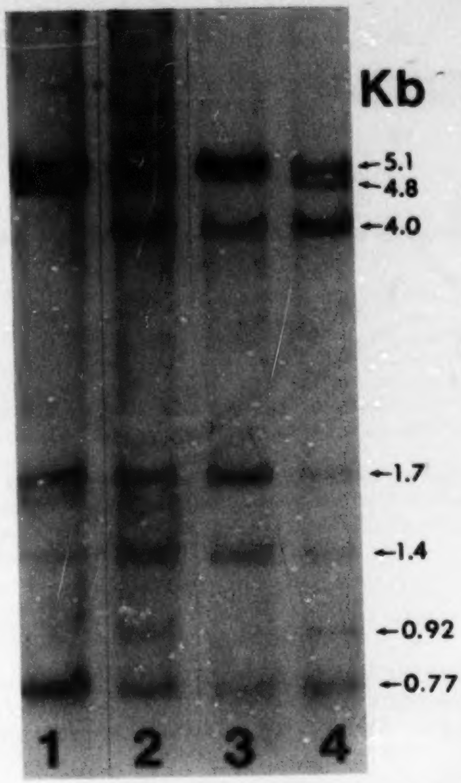

FIGURE 1.—Demonstration that the acquired proviruses in both high- and low-expressor DNA are exogenous MuMTV. Samples were digested with Pst I and analyzed as described in "Materials and Methods." The examples shown are: lane 1, BALB/c spleen; lane 2, low-expressor tumor 87B; lane 3, low-expressor tumor ZII; lane 4, high-expressor tumor 3525. *Numbers on the right* indicate the sizes of the fragments. The 0.92- and 4.0-kb fragments are characteristic of the presence of the exogenous C3H MuMTV (*5*).

2

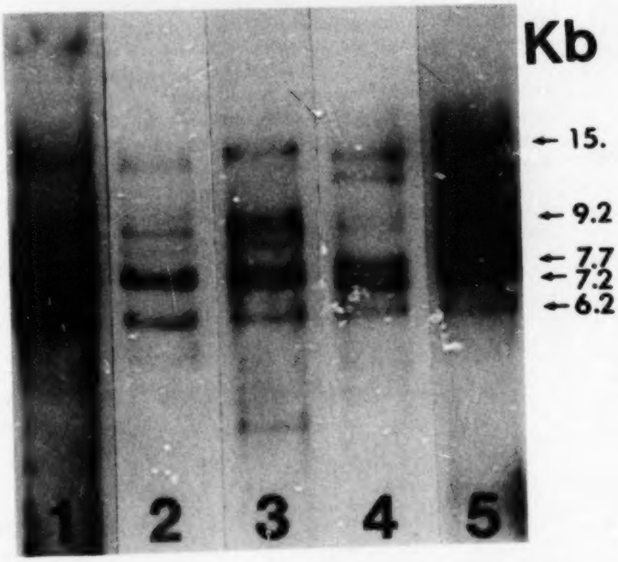

FIGURE 2.—Detection of acquired MuMTV proviruses in high-expressor and low-expressor tumor DNA. Samples are digested with Eco RI and analyzed as described in "Materials and Methods." The examples shown are: lane 1, BALB/c spleen; lane 2, low-expressor tumor ZII; lane 3, low-expressor tumor 3443; lane 4, high-expressor tumor 3800; lane 5, lymphoma 3373. *Arrows* identify fragments containing endogenous provirus sequences and give their sizes in kb.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Ions, Cell Proliferation, and Cancer Symposium

The National Cancer Institute and the W. Alton Jones Cell Science Center will sponsor this symposium to be held in Lake Placid, New York, on July 14–16, 1982. Subjects will include the roles of sodium potassium, calcium, and magnesium, pH, cyclic nucleotides and calcium-binding proteins in a wide variety of proliferating systems and in cancer development.

Information on speakers, submission of posters, registration, and accommodations may be obtained by writing to Dr. W. L. McKeehan, W. Alton Jones Cell Science Center, Old Barn Road, Lake Placid, New York 12946 (telephone: 518-523-2427).

Laser, Microwaves, Ultraviolet, and Ultrasound: Biophysical and Biological Basis, Applications, and Hazards in Medicine and Industry Program

The Massachusetts Institute of Technology Department of Mechanical Engineering and the Harvard-MIT Division of Health Science Technology will sponsor this program to be held at the Massachusetts Institute of Technology, Cambridge, Massachusetts, on August 9–13, 1982. The course will emphasize practical considerations in safe and effective use of these modalities in medical and industrial practice, e.g., methods and instrumentation for power measurement, calibration, dosimetry, compliance with Federal and State regulations, etc.

For additional information, please contact the Director of Summer Sessions, Room E19-356, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

Fourth Annual Pharmacy Symposium on Cancer Chemotherapy

Houston, Texas, will be the site of this meeting to be held at the Shamrock Hilton Hotel on September 12–14, 1982. The symposium will include sessions on cancer research status; patient psychotherapeutic management; hyperthermia; breast cancer update; DES daughters; and chemotherapy exposure risk. Workshop topics will include a patient panel, reconstructive surgery, death and dying, and bone marrow transplants. A seven-hour course entitled "Oncology Pharmacy: A Basic Course," designed for the new practitioner in oncology pharmacy, will also be held.

For additional information please contact Ms. Sharon Bronson, Department of Pharmacy, M. D. Anderson Hospital and Tumor Institute, 6723 Bertner Avenue, Houston, Texas 77030 (telephone: 713-792-2870).

A New Organization—American College of Epidemiology

A new organization for professional epidemiologists has been founded. The American College of Epidemiology is reviewing applications from individuals who have qualifying training and experience in epidemiology and who have made significant contributions to the study or practice of epidemiology. Membership categories include: Fellow, Associate, Affiliate, and International Fellow.

Dr. Abraham Lilienfeld was elected President of the College. Other Officers include Dr. Dwight Janerich, Vice-President; Dr. Curtis Mettlin, Secretary; Dr. Jess Kraus, Treasurer, and Dr. Jennifer Kelsey, Chairman of Membership Committee.

The goals of the College include the certification of epidemiologists who are trained and accomplished in the practice of their discipline, stimulating of education programs in epidemiology, and providing a forum for discussion of issues confronting the practice of epidemiology.

Persons interested in the programs of the American College of Epidemiology or in membership may obtain additional information from Dr. Curtis Mettlin, Secretary, American College of Epidemiology, % Roswell Park Memorial Institute, 666 Elm Street, Buffalo, New York 14263.

Annual Meeting of the American College of Epidemiology

Chicago, Illinois, will be the site of this meeting to be held at the O'Hare Inn, September 30–October 1, 1982. For further details please contact Dr. Curtis Mettlin, Secretary, American College of Epidemiology, Roswell Park Memorial Institute, 666 Elm Street, Buffalo, New York 14263.

International Cancer Symposium

ITR Biomedical Research of the University of Illinois, International Committee, and the Illinois Cancer Council will sponsor this symposium entitled "Cancer: Etiology and Prevention" to be held at the Pick Congress Hotel, Chicago, Illinois, on October 4–6, 1982.

The scientific program will emphasize research on the genetic characteristics of cancer at the cellular level, immunologic factors in susceptibility, and methods of chemo- and immunoprevention. Special sessions on reconciling the divergent points of view on the use of BCG as an immunoprophylactic agent are planned. All papers by invitation only.

The program will be of particular interest to experimental oncologists, clinicians, immunologists, radiologists, pathologists, oncology nurses, and those involved in cancer control. For further information please contact Dr. Ray G. Crispen, ITR Biomedical Research, University of Illinois, 904 W. Adams Street, Chicago, Illinois 60607.

Symposium on Application of Biological Markers to Carcinogen Testing

The U. S. Environmental Protection Agency will sponsor this symposium to be held at the Holiday Inn, Bethesda, Maryland, on November 15–19, 1982. This symposium will discuss the current status of biochemical and immunologicl markers to carcinogenicity with three main objectives: to review and update specific markers, to identify data gaps, and to recommend research goals. Sessions will encompass in vivo and in vitro systems, enzymes, oncofetal antigens and hormones, monoclonal antibodies, viruses, and DNA-adducts. Abstracts for poster sessions will be accepted until October 15, 1982.

For additional details please contact Ms. Claire M. Wilson, Associated Universities, Inc., Suite 603, 1717 Massachusetts Avenue, N. W., Washington, D. C. 20036 (telephone: 202-462-4475).

A New Journal—Survey of Immunologic Research

S. Karger Publishers announces the newest source of information for immunologists entitled *Survey of Immunologic Research*. This new journal began publication in April. It will provide scientists involved in immunology with an interpretative synthesis of selected topics drawn from the vast array of literature produced each year.

For further information or for sample copies please contact Mr. Paul Clark, S. Karger Publishers, Inc., 150 Fifth Avenue, Suite 1105, New York, New York 10011 (telephone: 212-924-9222).

Eighth FDA Science Symposium

"Recent Advances in Analytical Methodology in the Life Sciences" is the subject of this symposium to be held at the Uniformed Services University of the Health Sciences, 4301 Jones Bridge Road, Bethesda, Maryland, on August 16–18, 1982. The symposium will focus on recent advances being made in areas of analytical methodology—chemical, physical, instrumental, biochemical, physiological, etc.

Attendance is open to all interested parties and there is no registration fee. Interested investigators are invited to submit symposium-related abstracts which may be presented during the poster session. Poster abstracts should be transmittted for consideration no later than July 2, 1982.

For further information please contact Dr. Constantine Zervos, Office of Health Affairs (HFY-31), Food and Drug Administration, 5600 Fishers Lane, Rockville, Maryland 20857 (telephone: 301/443-4490).

Journal of the National
Cancer Institute

July 1982
Volume 69
Number 1

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols; *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083-2129) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221-245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3-10/Ann Intern Med 1979;90:95-99/Br Med J 1979;1:532-535/ or Lancet 1979;1:428-430).

UNITED STATES GOVERNMENT PRINTING OFFICE, WASHINGTON, D.C.: 1982

Table of Contents

Vol. 69, No. 1—July 1982

Investigations on Man

1 T-Lymphocyte and B-lymphocyte subpopulations infiltrating human mammary carcinomas — *Oleg Eremin, Robin R. A. Coombs, Terence D. Prospero, David Plumb*

9 Methionine regulation of *N*-5-methyltetrahydrofolate:homocysteine methyltransferase and its influence on the growth and protein synthesis in normal, neoplastic, and transformed cells in culture — *Jadwiga W. Tautt, Elżbieta L. Anuszewska, Jadwiga H. Koziorowska*

15 DNA distribution in human colon carcinomas and its relationship to clinical behavior — *R. C. Wolley, K. Schreiber, L. G. Koss, M. Karas, A. Sherman*

23 Circulating immune complex levels in patients with gestational trophoblastic neoplasia — *Anthony A. Rayner, Ross Berkowitz, Glenn Steele, Jr., Peter H. Schur, Mary L. Rodrick, Donald P. Goldstein, Paul J. Harte, Richard E. Wilson, Norman Zamcheck, Alelia E. Munroe*

Investigations on Nonhuman Systems

27 Decrease of tumor growth in mice after intravenous thymosin-treated bone marrow cell injection — *Didier Cupissol, Augustin Rey, Allan L. Goldstein, Bernard Serrou*

33 Relationship between xenotransplantability and cell surface properties of ascites sublines of a rat mammary adenocarcinoma — *Susan C. Howard, Steven R. Hull, John W. Huggins, Coralie A. Carothers Carraway, Kermit L. Carraway*

41 Steroid hormone receptors in the rat mammary adenocarcinoma induced by *N*-hydroxy-*N*-2-fluorenylacetamide — *Sara Antonia Li, Danuta Malejka-Giganti, Jonathan J. Li*

47 Platinum-complexed antitumor immunoglobulins that specifically inhibit DNA synthesis of mouse tumor cells — *Esther Hurwitz, Rina Kashi, Meir Wilchek*

53 Differences in spleen suppressor cell content in rats with progressing and regressing tumors — *Michael A. Hollingsworth, Donald L. Evans*

59 Gastrin protection against chemically induced gastric adenocarcinomas in Wistar rats: Histopathology of the glandular stomach and incidence of gastric adenocarcinoma — *Massaharu Tatsuta, Hisako Yamamura, Haruo Taniguchi, Hiroshi Tamura*

67	Subcutaneously injected radiolabeled liposomes: Transport to the lymph nodes in mice	*Vasily I. Kaledin, Nellie A. Matienko, Valery P. Nikolin, Yevgeny V. Gruntenko, Vladimir G. Budker, Tamara E. Vakhrusheva*
73	Prophylactic and therapeutic actions of supplemental β-carotene in mice inoculated with C3HBA adenocarcinoma cells: Lack of therapeutic action of supplemental ascorbic acid	*Giuseppe Rettura, Francis Stratford, Stanley M. Levenson, Eli Seifter*
79	Flow cytometric analysis of R3327 rat prostate adenocarcinoma grown in vivo and in vitro	*Alice J. Claflin, Alan Pollack, Theodore Malinin, Norman L. Block, George L. Irvin*
89	Depression of natural antitumor resistance of C57BL/6 mice by leukemogenic doses of radiation and restoration of resistance by transfer of bone marrow or spleen cells from normal, but not beige, syngeneic mice	*E. Gorelik, R. B. Herberman*
95	Spontaneous occurrence of atypical hyperplasia and adenocarcinoma of the uterus in androgen-sterilized SD rats	*Shinichi Morikawa, Souei Sekiya, Masabumi Naitoh, Hiroshi Iwasawa, Bin Takeda, Hiroyoshi Takamizawa*
103	Combined inhibitors of carcinogenesis: Effect on azoxymethane-induced intestinal cancer in rats	*Norman D. Nigro, Arthur W. Bull, Paulette S. Wilson, Barbara K. Soullier, Majid A. Alousi*
109	Generation of long-term T-lymphoid cell lines with specific cytotoxic reactivity for a syngeneic murine lymphoma	*Timothy J. Eberlein, Maury Rosenstein, Paul J. Spiess, Steven A. Rosenberg*
117	Pathogenesis of lesions induced in rat lung by chronic tobacco smoke inhalation	*Carol A. Heckman, Walden E. Dalbey*
131	Noncytolytic extraction of murine tumor-specific transplantation antigens with the nonionic detergent octyl-β-D-glucopyranoside	*Stephen J. LeGrue, Catherine M. Macek, Barry D. Kahan*
137	Use of young nude mice for selection of subpopulations of cells with increased metastatic potential from nonsyngeneic neoplasms	*Vincent A. Pollack, Isaiah J. Fidler*

T-Lymphocyte and B-Lymphocyte Subpopulations Infiltrating Human Mammary Carcinomas[1,2]

Oleg Eremin,[3,4] **Robin R. A. Coombs,**[3] **Terence D. Prospero,**[3] *and* **David Plumb**[3,5]

ABSTRACT—Both T- and B-lymphocytes were found in human primary mammary carcinomas and were distributed in widely varying amounts, but in most tumors, T-lymphocytes predominated. A small percentage of the T-lymphocytes expressed receptors for the Fc portion of IgG (FcγR), but very few had receptors for C3 ($C3^+$) (comparable to the findings in blood). A prominent subset of lymphocytes had FcγR and were $C3^+$, and most of these were surface immunoglobulin (sIg)-bearing cells. The majority of lymphocytes from this subset were Fc^+ $C3^+$, and only a small percentage were Fc^+ $C3^-$ (in contrast to the findings in blood). IgD and IgM were the predominant classes of immunoglobulin found on the B-lymphocytes. The different preparative techniques did not result in a selective loss of lymphocyte subsets, but collagenase digestion did lead to a loss of expression of the C3 receptor on the lymphocyte surface, which was recoverable when lymphocytes were reincubated at 37°C. No evidence was found for blocking of the C3 receptor by immune complexes with activated complement—JNCI 1982; 69:1–8.

The presence of lymphocytes within human solid tumors has been well documented histologically [for review, *see* (*1*)]. A prominent host infiltrative response has been found to be associated in many different types of solid tumors with an improved prognosis (*2–12*), suggesting a possible beneficial host antitumor response. The precise functions in vivo of these tumor-infiltrating lymphocytes, however, and in particular their possible role in controlling local growth and preventing metastatic tumor spread, are poorly defined.

We are in the process of investigating the immunologic reactivity and antitumor activity of lymphocytes within human mammary carcinomas. An integral part of our study is the characterization of the different lymphocyte subsets infiltrating these tumors, such knowledge forming an important background for the understanding of the various functional properties of these lymphocytes.

Although various groups of workers have published data on lymphocyte subsets infiltrating different human solid tumors (*13–19*), in most of these investigations various lymphocyte subsets were either incompletely characterized or not studied at all, and very few dealt comprehensively with malignant growths of the breast. In this publication we present our detailed findings on the T- and B-lymphocyte subpopulations infiltrating human mammary carcinomas and describe some of the artifactual alterations of lymphocyte receptors encountered with the enzymatic technique used to isolate the lymphocytes from the tumors. Our findings reveal a pattern of lymphocyte subsets, different in certain aspects, from the pattern previously described for lymphocytes in blood (*20*). Our results suggest a possible selective migration into and/or retention within these primary tumors of specific lymphocyte subsets (with specific functional properties, *see* "Discussion"), thus offering a possible explanation for "tumor escape" from immune defense mechanisms.

MATERIALS AND METHODS

Clinical material.—Patients were women between 40 and 70 years of age with a clinical stage I or II mammary carcinoma (confined to the breast and axilla) and who were undergoing mastectomy and axillary clearance as a potentially curative procedure. Lymph nodes were obtained from the axillary contents of the radical mastectomy specimens. Tonsils were obtained from patients undergoing tonsillectomy for recurring bouts of tonsillitis, which was quiescent at the time of surgery.

Tumor-derived lymphocyte preparations.—Mechanical disaggregation: The breast tumor specimen was obtained sterilely at surgery from the excised biopsy sample which had been sent for the frozen section biopsy examination. The tumor specimen (half of the excised growth) was cleared of fat and fascia and was washed in TCM consisting of RPMI-1640 medium with 10% heat-inactivated FCS, 25 m*M* HEPES[6] (pH 7.2), 0.7 g sodium bicarbonate/liter, 100 μg streptomycin/liter, and 100,000 IU penicillin G/liter. The specimen was then carefully cut (size 10 scalpel blades) into small, thin slices while it was in a small pot filled with TCM. Cells spilled out from the tissue slices during this procedure, and the cell-enriched supernatant was removed, filtered through sterile gauze layers for removal of residual stromal fragments, and then washed five times in TCM. This technique usually produced a low yield of viable cells.

Enzymatic digestion: The small, chopped-up tumor pieces were incubated in collagenase (type I; Sigma London Chemical Co. Ltd., London, England) at 37°C for 11–14 hours. (The enzyme solution was prepared by dissolving 300 U

collagenase/ml in protein-free TCM; this solution was filter sterilized and stored at −30°C.) The prolonged incubation of the tumor pieces produced a thick cell suspension, which was washed six times with TCM and passed through sterile gauze layers for removal of residual stromal fragments and debris. This procedure usually yielded a substantial number of viable cells ($5–50\times10^6$) which was primarily dependent on the size of the tumor specimen to be processed. The lymphocytes were isolated from such enzyme preparations by separation on Sephadex G-10 columns (*see* below). Lymphocyte numbers, viability, and contamination by macrophages and/or tumor cells were reassessed in the column eluate.

Non-tumor-derived lymphocyte preparations.—Blood: Venous blood from healthy adult volunteers was collected by venipuncture into syringes containing preservative-free heparin (30 IU/ml). Lymphocytes were isolated from the heparinized blood on a Ficoll–Hypaque gradient, washed, and suspended in TCM. Monocytes and polymorphonuclear leukocytes were removed from the mononuclear cell suspensiosns by incubation with carbonyl iron (37°C for 1 hr), and the phagocytic cells were removed with a strong magnet.

Lymph nodes and tonsils: Lymphocytes were isolated from the axillary lymph nodes and tonsils as previously described (*20*), and the phagocytic cells were removed as above.

So that the effect of collagenase digestion on lymphocyte viability and cell surface markers could be assessed, various lymphocyte preparations (1×10^7 blood, tonsil, or lymph node cells) were incubated with 15 ml collagenase type I (Sigma London Chemical Co. Ltd.) at 37°C for varying periods (30 min–24 hr). A previous study had revealed that separation of lymphocytes on Sephadex G-10 columns did not result in a selective loss of lymphocyte subsets (*21*).

Cell viability and morphology.—The viability of the cells in the various lymphocyte preparations was ascertained by phase-contrast microscopy, and the morphology of the cells (rosetted and nonrosetted) was determined by examination of wet slides of the mononuclear cell suspensions stained with toluidine blue, by cytocentrifuge preparations, and by dried smears fixed with methanol and stained with May-Grünwald-Giemsa and Sudan black.

Sephadex G-10 columns.—Sephadex G-10 columns, as described previously (*21, 22*), were used to isolate lymphocytes from enzymatically digested tumor cell preparations—the much larger macrophages and tumor cells being entrapped on the column. Occasionally, cell suspensions obtained by mechanical disaggregation were similarly separated.

Surface markers.—The various lymphocyte subsets were determined by the use of lymphocyte markers; this methodology has been outlined previously (*20*). The thymus-derived T-lymphocyte population was detected by the nonspecific SRBC-rosetting reaction (*23*). The T-lymphocyte subset with FcμR was determined by rosette formation with ORBC coated with a subagglutinating dose of rabbit IgM anti-ORBC antibody. Because of the as yet unexplained inhibitory effect of RPMI-1640 medium on the expression of FcμR on human lymphocytes [(*24*); Eremin O, Plumb D: Unpublished observations], both indicator cells and lymphocytes were finally resuspended in medium 199 (GIBCO) containing 10% heat-inactivated FCS, 100 μg streptomycin/liter, and 100,000 IU penicillin G/liter.

The sIg-bearing B-lymphocyte population and the various subpopulations bearing different classes of immunoglobulins (IgG, IgA, IgM, and IgD) were determined by the DARR as described by Coombs et al. (*25*). The same technique was used to couple sheep anti-human C3 and sheep anti-human C4 antibody to ORBC for use as indicator cells in detecting complement components on the lymphocyte surface.

The FcγR-bearing lymphocyte subset was detected by opsonic adherence of ORBC coated with a subagglutinating and an optimal dose of rabbit IgG anti-ORBC antibody (*26*). Complement receptor-bearing lymphocytes were estimated by rosette formation with ORBC sensitized with a subagglutinating and an optimal dose of rabbit IgM anti-ORBC antibody and C5-deficient mouse complement (*20*). Mixed rosetting reactions in which FITC-labeled indicator SRBC and/or ORBC were used have been outlined (*20*).

The class-specific sheep anti-human immunoglobulins and anti-human complement components (purified C3 and C4) were prepared at the Immuno-diagnostics Research Laboratory. The specificities of the immunoglobulin class-specific sheep antisera were characterized by reverse passive hemagglutination of indicator cells (ORBC linked with sheep antisera) with purified human immunoglobulins (*27*).

Statistical analysis.—Where relevant, the significance of a particular lymphocyte subset value was assessed by a one-way analysis of variance.

RESULTS

Non-Tumor-Derived Lymphocyte Preparations

Untreated.—Lymphocytes isolated from the blood of healthy controls and from tumor-free axillary lymph nodes and tonsils were 98% viable and free of contaminating phagocytic cells (≤3%).

Treated.—Incubation of blood lymphocytes at 37°C with collagenase for short periods (1–4 hr) resulted in minimal cell losses, but incubation for long periods (15–24 hr) resulted in substantial cells losses (30–50%). The final cell suspensions, however, were composed of viable lymphocytes (95%). It is obviously not possible in these experiments to reproduce exactly the conditions under which the tumor is digested by the collagenase. Minimal cell losses occurred during incubation of the various lymphocyte preparations in TCM at 37°C for 2–3 days. Lymphocyte suspensions were also passed through Sephadex G-10 columns, and a high percentage (>75%) of viable cells was recovered (*21*).

Tumor-Derived Lymphocyte Preparations

Mechanical disaggregation.—A variable but usually low yield ($<2\times10^6$) of viable cells (tumor cells, macrophages, and lymphocytes) and a correspondingly lower yield ($<1\times10^6$) of lymphocytes were obtained by this technique; however, most of the cells were necrotic and fragmented. Occasionally, mechanical disaggregation of tumors did produce substantial numbers of viable cells ($5–15\times10^6$) and lymphocytes ($2–10\times10^6$). In some instances the cell mixture was purified on Sephadex G-10 columns.

Enzymatic digestion.—Incubation with collagenase yielded a substantially larger number ($5–50\times10^6$) of viable cells (tumor cells, macrophages, and lymphocytes) from the tumor specimens. The total number of cells obtained from any specimen was determined primarily by the size of the tumor sample processed. The number of lymphocytes, relative to the other nonlymphoid cells (1:10–1:1) and in absolute terms ($1\times10^6–22\times10^6$), varied markedly from specimen to specimen. Breast tumors with a histologically recognizable and prominent lymphocytic infiltrate yielded the most lymphocytes when enzymatically digested. With many specimens the tumor-infiltrating lymphocytes were isolated from the tumor cell preparations by passage through Sephadex G-10 columns. An average of 44% (30–57%) of the tumor-infiltrating lymphocytes was recovered from the column in the eluate, and an average of 85% (76–94%) of the mononuclear cells eluted from the column was lymphocytes.

Lymphocyte Subpopulations Found in Human Mammary Carcinomas

Table 1 depicts the various lymphocyte subsets found in cell preparations obtained by different preparative techniques from human primary breast cancers. Comparable percentages of rosetting lymphocytes were obtained when both mechanical and enzymatic dispersion techniques were used on the same specimen, provided mechanical disaggregation yielded at least 10^6 viable lymphocytes. With lower yields of viable lymphocytes, discrepancies occurred between the techniques, suggesting that representative lymphocyte subpopulations were not being released from the tumor by the nonenzymatic method (data not shown). Rosetting reactions, depicted in table 1, were only done with lymphocytes prepared by mechanical disaggregation in which at least 10^6 viable lymphocytes were isolated.

The T-lymphocytes were the predominant lymphocyte subpopulation in each preparative group; however, the proportion varied widely among the different preparations, and in a few suspensions, it was less than the B-lymphocyte subset. The percentages of T-lymphocytes in the different cell preparations were comparable. Similarly, the sIg-bearing B-lymphocyte population was comparable in all preparative groups, although again like the T-lymphocyte subset above, the sIg-bearing B-lymphocyte population showed wide biological fluctuations.

The FcγR-bearing lymphocyte subset in the lymphocyte population isolated by collagenase digestion plus Sephadex G-10 passage, however, was just significantly lower ($P<0.05$) when compared with the subsets obtained by the other two preparative techniques. The higher percentages in the other 2 groups were probably due to prominent monocyte–macrophage contamination, which made accurate determination of the numbers of Fc$^+$ lymphocytes difficult and was not due to selective retention of the subsets on Sephadex G-10 columns (*21*, *22*).

The complement receptor-bearing lymphocyte subset was quite low in the cell preparations obtained by prolonged preincubation with collagenase. The lymphocytes obtained from breast tumors by mechanical disaggregation, however, had a significant percentage of C3$^+$ lymphocytes. This receptor expression suggested either that the collagenase treatment could selectively modify or remove the C3 receptor on the lymphocyte surface or that enzymatic digestion (with its much larger yield of lymphocytes) was freeing lymphocytes from within the tumor substances in which C3 receptors were blocked possibly by complement-containing immune complexes (*see* "Removal of C3 Receptor From Cell Surface by Preincubation of Lymphocytes With Collagenase").

The "null" cell population (lacking sIg and a receptor for SRBC), although higher than that normally found in lymphocyte suspensions from non-tumor-derived lymphoid compartments (*20*, *28*), was still on average low. Less than 10% of the total lymphocytes were isolated from the growths.

A substantial number (20–70%) of the nonlymphoid cells (predominantly macrophages and possibly some tumor cells) possessed FcγR and carried sIg—probably cytophilically acquired. These cells, characterized by morphology and in some instances by staining reactions with Sudan black, were excluded, as far as possible, from the determinations of the appropriate lymphocyte subpopulations. Also, a variable but at times a significant number (0–33%) of the nonlymphoid cells (macrophages) expressed receptors for C3, and these were also excluded from the determinations of the C3$^+$ lymphocyte subpopulations.

TABLE 1.—*T- and B-lymphocyte subpopulations infiltrating human mammary carcinomas*

Preparative technique	Rosetting lymphocyte subset[a]			
	T-rosettes	Fc rosettes	C3 rosettes	sIg rosettes
Collagenase digestion, *n*=20	64±18 (37–80)	22±10 (7–37)	4±5 (0–14)[b]	29±10 (14–45)
Collagenase digestion + Sephadex G-10, *n*=23	58±12 (34–83)	16±6 (10–30)[c]	5±5 (0–10)[b]	34±13 (12–57)
Mechanical disaggregation, *n*=11[d]	55±17 (24–77)	23±9 (13–36)	24±15 (5–60)	36±18 (9–68)

[a] Results are expressed as mean percentages ± standard deviations (ranges).

[b] Collagenase used in the preparative technique removed the C3 receptor, resulting in a very low C3-rosetting lymphocyte subset ($P<0.00001$; *see* tables 2, 3).

[c] This Fc-rosetting lymphocyte subset was just significantly lower ($P<0.05$) when compared with the other two Fc-rosetting subsets. The higher percentages were probably due to prominent monocyte–macrophage contamination in the other 2 groups, which made accurate determination of the numbers of Fc$^+$ lymphocytes difficult and was not due to selective retention of the subsets on Sephadex G-10 columns (*21*, *22*).

[d] Three samples of tumor-infiltrating lymphocytes were further purified with an additional passage through Sephadex G-10 columns. Lymphocyte preparations were used for rosetting reactions only when $\geq1\times10^6$ viable lymphocytes were isolated by the preparative technique.

C3 and C4 on Lymphocytes Isolated From Human Mammary Carcinomas

Table 2 reveals the presence of C3 and C4 on human tumor-infiltrating lymphocytes, as detected by rosette formation with sheep anti-human C3- and C4-coated ORBC, and their subsequent loss from the lymphocyte surface after incubation at 37°C for 48 hours in the absence of active complement. The highest percentage of rosettes was seen with lymphocytes obtained by mechanical disaggregation, and reduced percentages of rosettes were found with lymphocytes obtained by collagenase pretreatment. These data, therefore, suggest that receptor blockade was not the reason for the low levels of $C3^+$ lymphocytes found in enzymatic preparations of breast tumors.

The significance of the complement components C3 and C4 on tumor-infiltrating lymphocytes is uncertain. Surgical manipulation and trauma and contamination by blood and tissue fluids, with resultant activation of the complement cascade, may explain the presence of C3 and C4 on the isolated lymphocytes, even when mechanical disaggregation was done in the presence of EDTA, which prevents activation of complement.

Removal of C3 Receptor From Cell Surface by Preincubation of Lymphocytes With Collagenase

For the assessment of the effect of collagenase digestion on tumor-derived lymphocyte surface markers, lymphocytes from blood, tonsil, and lymph node were used as models. Table 3 shows that pretreatment of human lymphocytes with collagenase can result in the loss or possible modification of certain lymphocyte surface receptors, particularly when enzymatic digestion is prolonged. The receptor for SRBC (T-lymphocyte marker) on lymphocytes from tonsil and lymph node was susceptible, even when the incubation periods were short. Blood lymphocytes, contrariwise, required prolonged incubation with collagenase to strip off the receptor.

By the DARR assay, however, sIg was resistant to even prolonged (16 hr) collagenase treatment. The B-lymphocyte population isolated from breast tumors was therefore accurately enumerated. The null cell values in each tumor lymphocyte preparative group were low (*see* table 1), although the null cell values were higher than the values found in non-tumor-derived lymphocyte sources (*20*, *28*). Such values suggest that the enzymatic technique used for the isolation of tumor-infiltrating lymphocytes did not result in artifactual T-lymphocyte values.

The FcγR on lymphocytes from tumor-draining lymph

		Reincubation	42	6	47	43

[a] Six representative lymphocyte preparations are shown, although in each group five specimens were processed (*see* "Materials and Methods").

[b] Results are expressed as percentages for individual samples.

[c] Incubation of 10^7 lymphocytes was at 37°C for 4–16 hr in 15 ml TCM or collagenase (*see* "Materials and Methods"). After incubation with collagenase, lymphocytes were washed three times in TCM, and some cells were further incubated in TCM at 37°C for 48 hr (reincubation).

nodes and tonsils was highly susceptible to enzymatic digestion. The Fc receptor on blood lymphocytes, however, was resistant to collagenase digestion, although prolonged digestion (16 hr) was usually detrimental to a variable degree. Subsequent incubation in TCM at 37°C for 24–48 hours resulted in the full reexpression of the FcγR on blood lymphocytes but led to only a partial and much-reduced reexpression on lymphocytes from nodes and tonsils.

The C3 receptor on all the lymphocytes tested (irrespective of the lymphoid source) was highly susceptible to pretreatment with the collagenase used to isolate cells from breast tumors. In some instances, enzymatic digestion at 37°C for only 30 minutes resulted in significantly reduced detection of $C3^+$ lymphocytes (data not shown). Subsequent incubation at 37°C resulted in reexpression of the C3 receptor, presumably due to resynthesis of the receptor on the cell surface. This reexpression on blood lymphocytes was again complete after 24–48 hours, whereas with tonsil and lymph node lymphocytes, reexpression was substantial but was often incomplete, and the C3 receptors formed weak rosettes.

Effect of Incubation on Surface Receptors of Lymphocytes

Simple incubation (TCM, 37°C, 48 hr) of lymphocytes isolated from different lymphoid sources (non-tumor derived: blood, lymph node, and tonsil; tumor derived: enzymatically digested with collagenase) further exemplified the differential expression of certain receptors on lymphocytes from different lymphoid compartments.

Non-tumor derived.—No selective loss of T-lymphocyte (SRBC-rosetting) or B-lymphocyte (sIg-bearing) subpopulations occurred during the incubation. Examination of lymph node and tonsil lymphocytes, however, revealed reduced populations of cells expressing the FcγR on the cell membrane. Preincubation of blood lymphocytes, however, did not alter the percentage of FcγR-bearing lymphocytes. This difference probably explains the inability of lymph node and tonsil lymphocytes to reexpress fully the FcγR after pretreatment with collagenase and subsequent incubation in TCM (*see* table 3).

The percentage of measurable $C3^+$ tonsil lymphocytes tended to fall and the rosettes were weaker with reincubated lymphocytes, whereas the $C3^+$ lymph node lymphocyte subset was unchanged (3/5 specimens) or it increased (2/5 specimens). Incubation of blood lymphocytes resulted, in all instances (5 samples), in a prominent increase of the $C3^+$ subpopulation. The increase (blood, lymph node), however, was due to the incomplete expression of FcμR when incubation was with TCM containing RPMI-1640 medium at 37°C for 48 hours.

The FcμR-bearing lymphocyte subset was substantial (20–43%) in all lymphoid compartments studied. These maximal levels were only detected after the lymphocytes were incubated at 37°C and the rosetting assay was performed with the lymphocytes and indicator cells suspended in medium 199.

[a] Results are expressed as percentages of total rosettes counted. FITC-labeled indicator SRBC or ORBC were used (*20*).

[b] Tumor-infiltrating lymphocytes, isolated from collagenase-digested tumor and Sephadex G-10-passaged cells, were incubated in TCM at 37°C for 48 hr.

Tumor derived.—When lymphocytes isolated from breast tumors were incubated in TCM at 37°C for 48 hours, the previously low percentage of $C3^+$ lymphocytes was replaced by a substantially increased number of lymphocytes rosetting with the IgM complement-coated ORBC. Part of the increase was due to the expression of FcμR on the tumor-infiltrating T-lymphocytes (confirmed by rosetting with ORBC coated with rabbit IgM anti-ORBC and by mixed rosetting assays); maximal expression was not influenced by the diluent in which lymphocytes and indicator cells were suspended. The remainder of the rosette increase was due to the reexpression of C3 receptors on the lymphocyte surface. These findings substantiate further that the C3 receptors were degraded or removed from the lymphocyte cell surface by enzymatic digestion during cell preparations. This reexpression of the C3 receptor, in association with the lack of alteration of the FcγR during incubation, is comparable to the findings with blood lymphocytes (*see* "Non-tumor derived") and is indirect evidence that the tumor-infiltrative

lymphocyte originates from the intravascular compartment within the mammary tumor.

Characterization of Different T- and B-Lymphocyte Subsets by Mixed Rosetting Reactions on Tumor-Infiltrating Lymphocytes

Mixed rosetting reactions (table 4) showed that only a small number of the tumor-infiltrating T-lymphocytes had FcγR, i.e., were Tγ; most Fc^+ lymphocytes were sIg-bearing B-cells (*see* table 5). This finding was not altered by the preparative technique used (table 4).

Table 6 shows that there were virtually no T^+ $C3^+$ lymphocytes within breast carcinomas. Successful determinations of $C3^+$ lymphocytes could be done only with lymphocytes prepared by mechanical disaggregation of the tumor because enzyme treatment removed the C3 receptor and reincubation, even in RPMI-1640 medium, permitted expression of FcμR, albeit less readily than if the reincubation was in medium 199. The data in table 7 show that in both types of lymphocyte suspensions, prepared either by mechanical disaggregation or by collagenase digestion and Sephadex G-10 separation with reincubation in TCM at 37°C for 48 hours, most of the Fc^+ lymphocytes were also $C3^+$. However, a small percentage (low absolute number) was Fc^+ $C3^-$ lymphocytes, but this percentage was less than the level previously found for blood (*20*), suggesting a selective migration into and a retention and/or proliferation within the mammary tumor of various lymphocyte subsets.

TABLE 7.—*Fc^+ and $C3^+$ subsets of tumor-infiltrating lymphocytes*

Breast tumor specimen	Preparative technique	Mixed rosetting reactions[a]		
		Fc rosettes, $Fc^+ C3^-$	Mixed rosettes, $Fc^+ C3^+$	C3 rosettes, $Fc^- C3^+$

2	Mechanical disaggregation	17	73	10
3	Collagenase digestion and reincubation[b]	22	60	18
4	Collagenase digestion and reincubation[b]	15	43	32

[a] Results are expressed as percentages of total rosettes counted. FITC-labeled indicator ORBC were used (*20*).

[b] Tumor-infiltrating lymphocytes were isolated from collagenase-digested tumors, passaged through Sephadex G-10 columns, and were reincubated in TCM at 37°C for 48 hr.

Most of the tumor-derived lymphocytes with FcγR were determined by mixed rosetting assays to belong to the sIg-bearing B-lymphocyte subpopulation. This data is presented in table 5.

Classes of Immunoglobulins Present on Tumor-Infiltrating Lymphocytes

As can be seen from table 8, the spectrum of immunoglobulin classes present on lymphocytes isolated by enzymatic digestion or mechanical disaggregation from breast cancers was similar: IgD and IgM were predominant. The elevated level of IgG-bearing cells in cell suspensions from mechanically disaggregated tumors was probably due to absorbed or cytophilically acquired immunoglobulin because a variable but small number of macrophages was present in the cell suspensions not preincubated at 37°C before the rosetting assay was performed. However, no statistically significant differences were detected when the relevant immunoglobulin class-specific rosettes of the two different preparative groups were compared.

DISCUSSION

The present study has shown that both T-lymphocyte subsets and sIg-bearing B-lymphocyte subsets infiltrate human primary mammary carcinomas. A wide range of values was determined for both the T- and B-lymphocyte populations, but T-lymphocytes were predominant in most specimens studied. This pattern was seen in all the tumor-derived

Preparative technique	Lymphocyte rosettes[a]				
	sIg[b]	IgG	IgM	IgA	IgD
Collagenase digestion + Sephadex G-10, $n=8$	34±14 (12–56)	8±6 (2–17)	16±15 (4–50)	8±6 (1–20)	15±10 (2–25)
Mechanical disaggregation, $n=4$	30±8 (22–35)	12±4 (7–13)[c]	12±6 (7–18)	6±4 (2–11)	17±9 (5–25)

[a] Results are expressed as mean percentages ± standard deviations (ranges). No statistically significant differences were detected by a comparison of the relevant immunoglobulin class-specific rosettes of the 2 preparative groups.

[b] The sIg is expressed as total immunoglobulin.

[c] Cell suspensions obtained from mechanically disaggregated tumors were not preincubated at 37°C before the rosetting assays were performed, which may account for the elevated levels of IgG-bearing lymphocytes detected.

lymphocyte preparations, irrespective of the techniques used for isolation of the tumor-infiltrating lymphocytes. The findings presented in this paper not only confirm some of the published data on T- and/or B-lymphocyte subpopulations infiltrating different types of human solid tumors (*15–18, 29–33*) but also document much more fully and define more precisely the various lymphocyte subpopulations found in malignant growths of the breast.

Mechanical disaggregation, because of its low yield of viable cells, was generally found to be an unsatisfactory technique for isolating tumor-infiltrating lymphocytes from breast tumor specimens. Most cancers were scirrhous and were associated with a prominent stromal reaction; as such, they required enzymatic digestion with collagenase. Häyry and Tötterman (*17*), for humans, and Russell et al. (*34*), for mice, similarly found collagenase to be a satisfactory enzyme for preparation of cell suspensions from solid tumors.

The preparative techniques used in the present investigation did not appear to destroy tumor-infiltrating lymphocyte subsets selectively, but collagenase digestion did alter and probably removed the C3 receptor on lymphocyte surfaces. Continued incubation at 37°C for 48 hours usually resulted in reexpression of C3 on the lymphocyte surface, and although the complement components C3 and C4 were detected on the surface of a variable percentage of the tumor-infiltrating lymphocytes, our inability to detect the C3 receptor (by the rosette assay) on lymphocytes isolated from enzymatically digested tumor specimens was not due to receptor blockade. Pretreatment of non-tumor-derived lymphocytes (e.g., from blood, lymph node, or tonsil) with collagenase type I (Sigma London Chemical Co. Ltd.) did lead to differential losses of the various lymphocyte surface receptors, particularly when incubation was prolonged, and the C3 receptor was especially susceptible.

The $C3^+$ lymphocyte subset therefore was quite prominent among the tumor-infiltrating lymphocytes. Most of the $C3^+$ lymphocytes within the mammary tumors were shown by mixed rosetting reactions to be a subset of the sIg-bearing B-lymphocyte population. Complement receptor-bearing cells infiltrating human cancers have also been described by C[illegible] et al. (*29*), for skin tumors, and by Catalona et al. ([illegible]), for bladder neoplasms, but we were unable to find reports in the literature of such lymphocyte subsets infiltration mammary carcinomas. Our investigations have also revealed the presence of tumor-associated immunoglobulin (Eremin O, Plumb D: Unpublished observations) suggesting an in situ antitumor humoral response. The specificity and beneficial (or otherwise) effect of such a response, however, remain to be carefully evaluated.

Fc lymphocyte subsets obtained from breast cancer tissue did not appear to have collagenase-digestable Fc receptors. Although Fc^+ subsets were prominent, far fewer Fc^+ cells were found in tissue digests than were found in the blood of patients with breast cancers (*20*). In 1979, Vose and Moore (*19*) also described Fc^+ lymphocytes infiltrating mammary carcinomas. They, as well as Häyry and Tötterman (*17*), have found FcγR lymphocytes infiltrating a variety of human solid tumors (*16, 17, 19*). In the present study, we further characterized this lymphocyte subset by mixed rosette assays, which revealed that most FcγR lymphocytes belonged to the sIg-bearing population and were Fc^+ $C3^+$ cells; a smaller percentage was Fc^+ $C3^-$. This Fc^+ $C3^-$ tumor-derived subset was much smaller than an identical subset previously found in lymphocyte preparations from blood (*20*). This result, when compared to our previous findings (*36*), suggested a paucity of killer K-lymphocytes and NK lymphocytes infiltrated mammary carcinomas. This lack of K-cell and NK cell cytotoxicities was confirmed by the findings of a concurrent study (*37*), which establishes the importance of the present data and their notable correlation with some of the functional studies done to date. Lack of appropriate cytotoxic cells within breast tumors, although appropriate cytotoxic cells are present in significant numbers in the blood of breast tumor patients, may be partly responsible for continued tumor growth. The T-lymphocyte population isolated from the breast tumors was found in the small number of samples tested to have a small subset of Tγ and a much larger subset of Tμ lymphocytes. The range of Tγ levels is comparable to that of Tγ levels found in blood (Eremin O, Plumb D: Unpublished data), but a larger series of samples is necessary to confirm the lower range of Tμ levels found within tumors compared to the range of Tμ levels detected in blood (Eremin O, Plumb D: Unpublished data). Thus lymphocyte subsets in which both the T-suppressor and the T-helper cells are found (*38*) are present within human mammary tumors. Because of some Fc receptor overlap between helper and suppressor populations and because of the ease with which receptors are modulated on the T-lymphocyte surface, a rigid functional classification based on the reactivities of IgG and IgM receptors on T-lymphocytes may not be correct in some instances.

Bustamante et al. (*32*) and De Panfilis et al. (*33*) described some of the classes of immunoglobulins found on B-lymphocytes infiltrating skin cancers. Their findings are at variance with our data. In our study, IgD and IgM were the predominant classes detected. However, differences may exist between the different pathologic types of solid growths. This intertumor difference is partly suggested by the total absence of IgM-bearing lymphocytes infiltrating malignant melanoma (*32*) and their obvious presence in tumor infiltrates of carcinoma of the breast (*39*).

From the specimens used in the study, no obvious correlation between various tumor parameters (e.g., size, grade of malignancy, or spread to lymph nodes) and the spectrum of lymphocyte subsets was detected. All the data presented, however, were obtained from clinically localized malignant growths—breast tumors with or without metastatic spread to axillary nodes. Metastatic spread of tumor to the regional lymph nodes had no obvious effect on rosetting patterns detected, a finding similar to that described previously for lymphocyte subpopulations of tumor-draining lymph nodes (*20*).

Lymphocytes infiltrating mammary carcinomas presumably migrate into the tumor cell milieu from the intravascular compartment of the tumor, but factors responsible for such cell fluxes are as yet poorly defined (*40–42*). Differential alterations of surface marker profiles for tumor-derived and non-tumor-derived lymphocytes, obtained after digestion with collagenase and/or incubation for prolonged periods at 37°C, suggest that tumor-infiltrating lymphocytes probably originate from the circulating intravascular compartment.

Methionine Regulation of *N*-5-Methyltetrahydrofolate:Homocysteine Methyltransferase and Its Influence on the Growth and Protein Synthesis in Normal, Neoplastic, and Transformed Cells in Culture[1,2]

Jadwiga W. Tautt,[3] Elżbieta L. Anuszewska,[3] *and* Jadwiga H. Koziorowska[3]

ABSTRACT—Normal human embryonic fibroblasts (CLV-58) and normal embryonic rat fibroblasts (REF) revealed equal growth in media containing 0.2 m*M* DL-homocysteine thiolactone (HOM) or in methionine (METH) enriched with 1.5 μ*M* cyanocobalamin and 0.1 m*M* folic acid, whereas L 5178Y lymphoblasts and transformed rat fibroblasts (REF-S) showed more or less acute need for exogenous METH. In normal cells general protein synthesis remained unimpaired during 24 hours after substitution of METH by HOM. In L 5178Y and REF-S cells, however, protein synthesis was significantly inhibited. Measurements of *N*-5-methyltetrahydrofolate:homocysteine methyltransferase revealed a two- to threefold increase of enzyme activity in normal cells grown on HOM and in L 5178Y and REF-S cells grown on HOM with added METH. HeLa cells showed variability in growth pattern, in general protein synthesis response, and in inducibility of methyltransferase upon substitution of METH by HOM.—JNCI 1982; 69:9–14.

The enzymatic biosynthesis of METH, its mechanism, and regulation have been the subject of many studies. In animal tissues the final methyl transfer reaction that converts HOM to METH is catalyzed by mTHF:HOMmTase (EC 2.1.1.5). Due to the activity of this enzyme, METH requirements of whole animals (*1*) and cells cultured in vitro (*2*) can be met by nutrients that contain HOM, folic acid, and vitamin B_{12} without added METH.

In the course of the search for metabolic differences between normal and neoplastic cells, it was demonstrated that eight cell lines derived from normal tissues show equal growth in medium that contains either METH or HOM (*3–8*). This was not the case with FL amnion cells (*4*); however, these cells are heteroploid and exhibit HeLa cell markers. The findings presented in the above studies as well as in the studies of Chello and Bertino (*9*) also show that Walker carcinosarcoma 256, mouse 5178Y lymphoma, mouse lymphatic leukemia L 1210, P 1815 mastocytoma, human monocytic leukemia J 111, human lymphoblastic leukemia CCRF-HSB-2, lung adenocarcinoma A-549, and two human virus-transformed cell lines all exhibit absolute METH requirement for cell growth in culture. These observations are in contrast with the earlier results (*2, 10*) that indicate that HEP-2 and HeLa cells exhibit comparable growth on METH and HOM. It is difficult to establish the validity of these experiments because the authors used undialyzed serum in their experiments that could have provided sufficient amounts of METH for cell growth. Recently, Kreis and Goodenow (*8*) concluded that a general discrimination between benign and malignant tissue on the grounds of capability of a nutritional replacement of METH by HOM is not applicable for human neoplastic cells. They found that three cell lines derived from human tumors including HeLa cells showed comparable growth in both kinds of media. In recent studies we have demonstrated that cells from methylcholanthrene-induced unpassaged rat sarcomas behave similarly in METH-deprived culture medium and in medium without METH but supplemented with HOM, folic acid, and vitamin B_{12} (*11*).

The activity of mTHF:HOMmTase was shown to be dependent on the level of vitamin B_{12} (*12, 13*), folic acid (*14*), and METH (*13, 15*). Studies of Kamely et al. (*3*) demonstrated that in BHK cells mTHF:HOMmTase activity increased 2.5- to 4.0-fold over the highest levels obtained in the presence of METH, B_{12}, and folic acid when HOM was substituted for METH in the growth medium. This enzyme activity increase was blocked by puromycin. BHK cells showed equal growth in medium that contained either METH or HOM. Taylor and Hanna (*16*) have analyzed the effects of cyanocobalamin, L-METH, folic acid, DL-mTHF and other nutrients on mTHF:HOMmTase in CHO cells and their mutants. The mutants were distinguished from CHO cells by their incapability to grow and survive when HOM was substituted for METH. The authors concluded that the level of mTHF:HOMmTase induced by high medium folate concentrations is a critical determinant of CHO cell survival in METH-free media.

In the present study we attempted to determine biochemical events that correlate with METH auxotrophy of cells in culture. For this purpose we analyzed the effects of METH depletion or decrease and HOM addition on the growth of normal, transformed, and neoplastic cells in culture. We also determined the response of general protein synthesis to these media changes and measured the levels of mTHF:HOMmTase in cell extracts. Since the increase of mTase activity upon METH substitution by HOM requires concomitant protein synthesis (*3*), we have assumed that substitution of METH by HOM may lead to impairment of protein synthesis in certain cells, diminishing the enzy-

matic formation of METH to amounts that are insufficient for the growth and survival of these cells.

MATERIALS AND METHODS

Cell lines.—HeLa and L 5178Y cells were cultivated in our laboratory for several years. Normal human CLV-58 cell line was obtained by standard methods. REF were derived from 19-day-old embryos of Sprague-Dawley rats. REF-S cells were spontaneously transformed counterparts of REF cells. In a series of experiments we ascertained that the cells produced fibrosarcomas in 100 percent of animals when inoculated into newborn Sprague-Dawley rats.

Culture methods.—All cells, with the exception of L 5178Y lymphoblasts, were grown routinely in flasks in commercially available EMEM 1959. L 5178Y cells were cultured in suspension in Fischer's medium without stirring. The media were reinforced with 10 or 8% calf serum, respectively, previously dialyzed for 24 hours at 4°C against three changes of a solution containing 8 g NaCl, 0.4 g KCl, 1 g glucose, and 0.35 g $NaHCO_3$ per liter and supplemented with 100 µg streptomycin sulfate/ml and 100 U penicillin G/ml. The dialyzed calf serum was analyzed by a microbiological method using Leuconostoc mesenteroides P 60 to ascertain its METH contribution to the media. Only a trace amount of METH was found in the dialyzed serum. For three passages prior to the experiments all cell types were cultivated in media enriched with 1.5 µ*M* cyanocobalamin and then harvested, washed, and transferred into experimental media. During the course of the studies, the cells were repeatedly checked by the method of Chen (*17*) to assure that they were free of Mycoplasma contamination.

Experimental media.—The basic experimental media consisted of EMEM and Fischer's medium without METH and folic acid. During the experiments, 0.2 m*M* DL-homocysteine thiolactone was added to the media enriched with 1.5 µ*M* cyanocobalamin and 0.1 m*M* folic acid. All media were reinforced with dialyzed calf serum, 10 or 8% respectively, and with different amounts of METH where indicated.

Growth rate and viability.—Growth rate was assessed every 24 hours during 3 days by determination of cell numbers. Triplicate cell counts, in agreement within ±10%, were averaged to plot the cell growth pattern. The data presented in the text are means from 5–6 studies performed for each type of culture. Viability of the cells was checked by the trypan blue exclusion test.

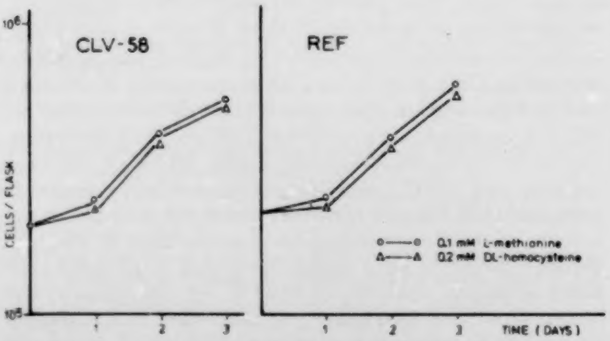
Enzyme preparation and assay.—All cells, with the exception of L 5178Y cells, were released from the surface by trypsin. Trypsinization was stopped by addition of the serum-containing medium. All cells were washed twice in PBS (pH 7.2), suspended in phosphate buffer (pH 7.4) that contained 0.01 *M* of reduced glutathione, and disrupted in a sonic oscillator (MSE-MK 2; MSE, 25–28 Buckingham Gate, London S.W.I. England). The debris was removed by centrifugation at 20,000×*g* for 30 minutes and the supernatant was assayed for mTHF:HOMmTase activity. Protein concentration was measured by the method of Lowry et al. (*18*) in each sample.

The activity of mTHF:HOMmTase was determined by measurement of [^{14}C]METH formation from [5-^{14}C]mTHF as described by Kamely et al. (*3*). A standard reaction mixture contained in a total volume of 0.200 ml was 100 m*M* phosphate buffer (pH 7.4), 125 m*M* 2-mercaptoethanol (Fluka, Buchs, Switzerland), 250 µ*M* (−)-s-adenosyl-L-methionine iodide (Calbiochem-Behring Corp., La Jolla, Calif.), 50 µ*M* cyano-B_{12} (Sigma Chemical Co., London, England), 250 µ*M* DL-HOM (Serva Feinbiochemica GmbH, Heidelberg, Federal Republic of Germany) prepared just before use from the thiolactone derivative, 100 n*M* [5-^{14}C]mTHF (sp act, 57 mCi/m*M*; Amersham International Ltd., Amersham, England), and 100 µl of cell extract. The reaction mixtures were incubated for 1 hour at 37°C and the reaction terminated by addition of 0.8 ml of ice cold water. The mixtures were passed through a Dowex 1-Cl (SERVA) column, that retained [5-^{14}C]mTHF and washed with an additional 1.0 ml water. The [^{14}C]METH thus formed was measured in the pooled effluent by counting an aliquot in a toluene-Triton-X-100-2,5-diphenyloxazole, (PPO) and 1,4-bis[2-(5-phenyloxazolyl)]benzene (POPOP) solution with a liquid scintillation spectrometer (LS 3150 P; Beckman Instruments Inc., Cedar Grove, N.J.). Specific activities were expressed in nmoles of METH formed per milligram protein per hour at 37°C and were the average of three determinations with a variation of less than 10%.

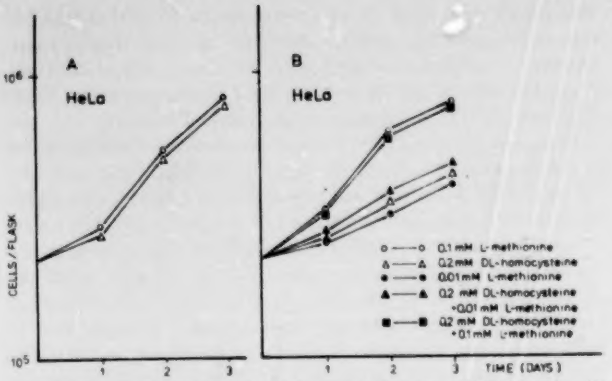
Determination of protein synthesis.—For studies of protein synthesis a number of parallel cultures were seeded at 1–2×10^4 cells per flask and grown in 2 ml of experimental culture medium. At definite time intervals, every monolayer culture was labeled for 30 minutes with 1 µCi of L-[H^3]-valine/ml (sp act, 2 Ci/mmol; Amersham International Ltd.). We stopped incorporation by decanting the pulsing medium, washing the cultures five times with cold Earle's salt solution, and dissolving the cells in 0.5 ml of 1 *N* NaOH. After 20 minutes at 37°C, 1 ml of 20% trichloroacetic acid was added to precipitate the cell protein. The precipitate was collected on Millipore filters (Millipore Corp., Bedford, Mass.) and counted in a toluene-based scintillation fluid. L 5178Y cells were centrifuged at 120×*g* for 10 minutes, washed three times, dried, and processed as indicated above. The radioactivity of all samples was measured with a Beckman LS 3150 P liquid scintillation spectrometer.

RESULTS

All cell types were studied several times in the course of



TEXT-FIGURE 1.—Growth of REF and CLV-58 cells in media containing L-METH, or DL-HOM without METH. *Abscissa:* time in days after inoculation. *Ordinates:* cell growth as evaluated by number of cells per flask.



TEXT-FIGURE 2.—Variations in the growth pattern of HeLa cells. A) Growth of HeLa cells in media containing L-METH or DL-HOM without METH, or B) in the same media and in media with DL-HOM and L-METH added at indicated concentrations. *Ordinates and abscissa* are as in text-fig. 1.

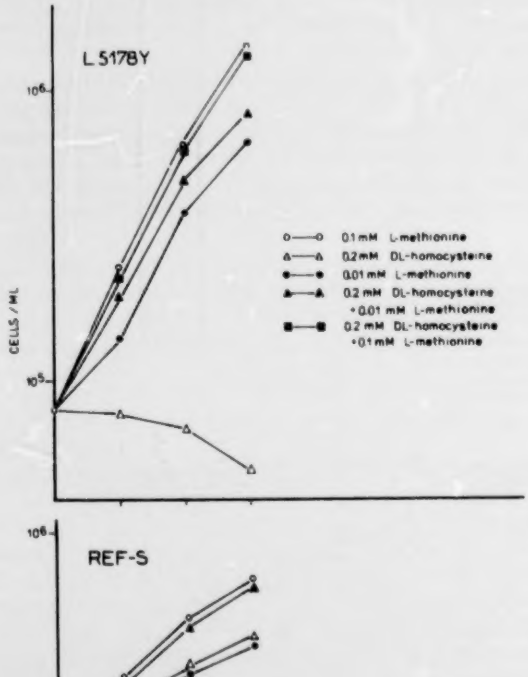
passaging. The CLV-58 normal human embryonic fibroblasts and REF showed unimpaired growth independently of the passage level investigated (from 5 to 20 for CLV-58 cells and from 4 to 10 for REF cells) in the medium devoid of METH but supplemented with HOM and enriched with cyanocobalamin and folic acid (text-fig. 1). In contrast to the earlier findings (*8*), HeLa cells revealed varied responses to substitution of METH by HOM. In successive sets of experiments performed at intervals of several weeks, the cells showed either unimpaired rate of growth on HOM (text-fig. 2A) or their growth on day 3 decreased to about 50% of the control level (text-fig. 2B). The decrease in growth rate could be reversed and brought back to control levels in the presence of 0.1 m*M* METH. L 5178Y cells (text-fig. 3) revealed the reported inability of growth (*3*) on HOM unless it was enriched with 0.1 m*M* METH. Text-figure 3

TABLE 1.—*mTHF:HOMmTase activities in various cell types*

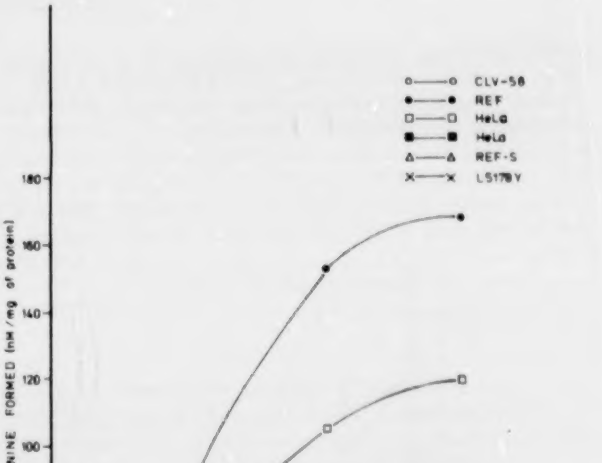
Cell line[a]	METH formed/mg of protein/hr, nmole ± SE[b]
CLV-58	24.5±4.9
REF	54.8±9.3
REF-S	32.0±6.2
HeLa	38.8±7.8–48.8±8.8
L 5178Y	15.0±3.1

[a] Cells were grown in the basic media containing 0.2 m*M* DL-HOM, 1.5 *μM* cyanocobalamin, and 0.1 m*M* folic acid.

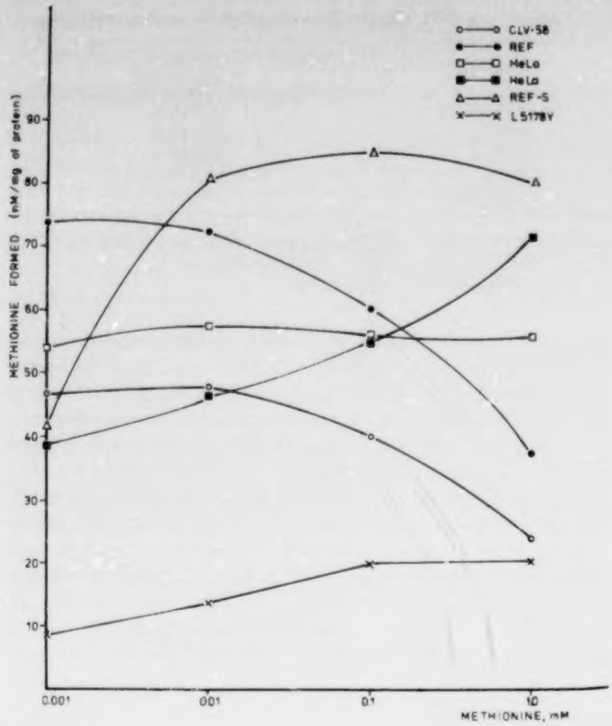
[b] Mean values of 5–6 measurements.



TEXT-FIGURE 3.—Growth of REF-S and L 5178Y cells in media containing L-METH, or DL-HOM without METH, or DL-HOM and L-METH. *Ordinates:* cell growth as evaluated by the number of cells per flask for REF-S cells or by the number of cells per ml for L 5178Y cells. *Abscissa:* time after inoculation.



TEXT-FIGURE 4.—mTase activity in cell extracts after refeeding with METH-deficient medium. Cells were grown in media supplemented with 0.1 m*M* folic acid, 0.2 m*M* DL-HOM, and 1.5 *μM* cyanocobalamin.



TEXT-FIGURE 5.—Effect of METH concentration on the specific activities of mTase. Cultures were inoculated for 24 hr in EMEM or Fischer's medium containing DL-HOM and various amounts of L-METH and then assayed for enzyme-specific activities.

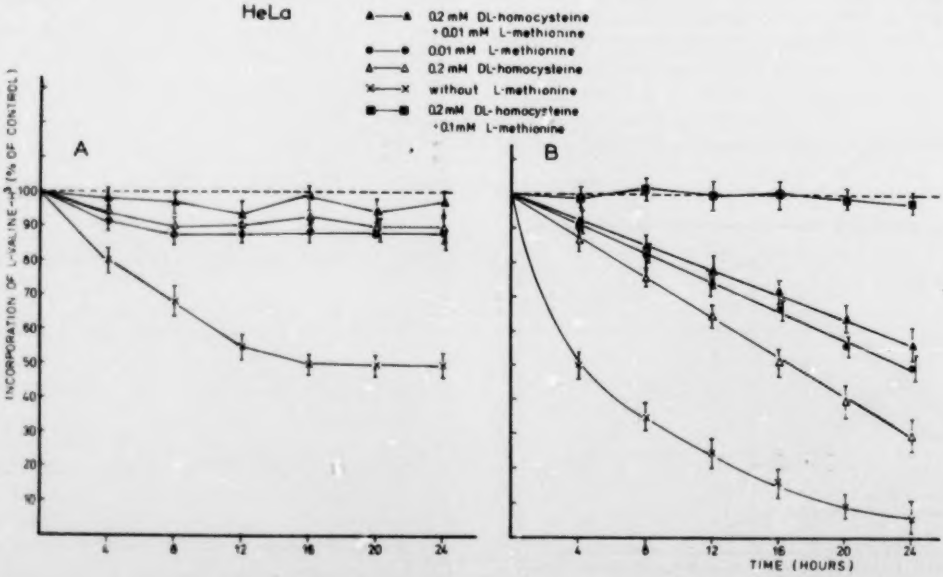
also shows that REF-S, grown in media in which METH was substituted by HOM, exhibited growth impairment: On day 3, growth rate decreased to about 60% of controls. A concentration of 0.01 m*M* of METH improved the REF-S growth rate to reach that of the control cultures.

Measurements of mTHF:HOMmTase activity.—Specific activity of the enzyme was twice as great in REF than in CLV-58 and REF-S cells in analogous culture conditions (table 1). L 5178Y cells showed rather low specific enzyme activity.

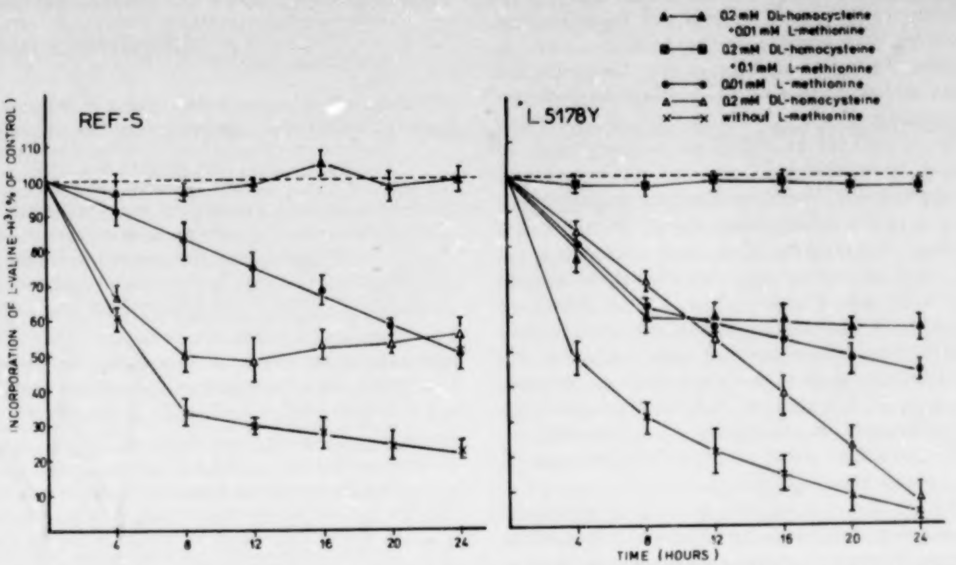
After substitution of HOM for METH, the enzyme activity remained at about the same level for 6 hours in all the cell cultures (text-fig. 4), then in REF and CLV-58 cells it increased threefold over the next 30 hours as compared to zero time. In contrast, in L 5178Y cells enzyme activity did not show any increase during 24 hours. At 36 hours the mTHF:HOMmTase activity was not measured in L 5178Y cells because of a gradual loss of cell viability under these culture conditions. REF-S cells showed a rather small but significant ($P<0.05$) increase of specific enzyme activity.

The experiments performed at different time intervals revealed that in HeLa cells the specific activity of mTHF:HOMmTase remained unchanged or increased to a value 2.5 times higher than that at zero time.

Text-figure 5 shows that increase of the METH levels from 0.001 m*M* to 0.1 m*M* in the HOM-containing medium raised B_{12}-mTase activity in REF-S and L 5178Y cells twofold. However, the optimal level of METH for a twofold increase in L 5178Y cells was ten times higher than that in REF-S cells. In contrast, supplementation of the media with increasing amounts of METH led to a gradual repression of the enzyme activity in normal CLV-58 and REF cells. Text-figure 5 also shows that in HeLa cells METH either did not



TEXT-FIGURE 6.—Variability in the response of general protein synthesis in HeLa cells. A) Protein synthesis in HeLa cells cultured in EMEM without L-METH and in EMEM with 0.2 m*M* DL-HOM without METH. B) Protein synthesis in HeLa cells cultured under the same conditions as in panel A and additionally in EMEM containing 0.2 m*M* DL-HOM and 0.01 m*M* or 0.1 m*M* METH. Protein synthesis was measured by [^{3}H]valine incorporation. Synthesis is expressed as percentage of control value; each point is the mean of triplicate aliquots.



TEXT-FIGURE 7.—Protein synthesis in REF-S and L 5178Y cells cultured in EMEM or in Fischer's medium without L-METH, or in EMEM with 0.2 m*M* DL-HOM without L-METH, or DL-HOM and L-METH, respectively, at the concentrations indicated. Experiments were performed and the synthesis was estimated as indicated in text-fig. 6.

influence enzyme activity or with increasing levels raised it progressively.

Measurements of protein synthesis.—We performed these experiments to determine whether or not cell growth response differences that were due to changes in the media content were correlated with differences in the protein synthesis response.

After METH was substituted for HOM, protein synthesis in HeLa cells either remained unimpaired (text-fig. 6A), or was significantly inhibited ($P<0.001$) (text-fig. 6B). In this series of experiments as much as 0.1 m*M* METH was needed to prevent inhibition of protein synthesis. It is evident from text-figure 6 that the protein synthesis response to exogenous METH deprivation also showed a significant ($P<0.01$) degree of variation.

Inhibition of protein synthesis in REF-S cells was noticeable already 4 hours after METH deprivation, and it declined to 20% of the control level at zero time after 24 hours (text-fig. 7). Substitution of METH by HOM caused the level of protein synthesis to fall about 60% of the control level at zero time in 24 hours. When cells were incubated in medium with 0.01 m*M* METH, the valine incorporation declined to levels similar to those observed in medium with HOM but without METH. However, in the presence of HOM and 0.01 m*M* METH, protein synthesis was unaffected. In L 5178Y cells the inhibition of valine incorporation was complete after 24 hours both in medium without METH and in medium without METH but containing HOM. In cells that were cultivated on HOM, ten times as much 0.1 m*M* METH was needed to restore protein synthesis.

In both types of normal cells, CLV-58 and REF, grown in medium devoid of METH, protein synthesis remained unaffected for the period of 24 hours.

DISCUSSION

Conflicting views have been presented to explain differences in the capacity of mammalian cells to grow in culture media that contain HOM instead of METH. Ashe et al. (*4*) demonstrated that adult normal cell extracts have a higher proportion, about 75%, of their total mTHF:HOMmTase in the holoenzyme form, whereas all neoplastic cell and embryonic cell extracts have less than 45% of their enzyme in this form. On the basis of this evidence, they claimed that neoplastic cells may have one or more defects that prevent them from using HOM in place of METH for growth and survival. Other studies (*7*) indicate, however, that neoplastic and transformed cells, although they are METH auxotrophs, do synthesize METH endogenously from mTHF at rates that are at least as high as in normal cells. These findings led the authors to conclude that there was one or more specific functions in neoplastic and transformed cells that can only be fulfilled by exogenous METH.

In our studies normal human and rat fibroblasts did not change their growth rate upon replacement of METH by HOM and supplementation of medium with folic acid and vitamin B_{12}. In the presence of HOM the growth of REF-S and L 5178Y cells remained unimpaired when METH was added to the medium. HeLa cells were either dependent or independent of exogenous METH.

Measurement of mTHF:HOMmTase activity showed a two- to threefold increase in CLV-58 and REF upon substitution of METH by HOM, whereas in L 5178Y cells and REF-S a similar increase in enzyme activity occurred only when the cells were grown on HOM with added METH. HeLa cells showed a twofold increase of enzyme activity in some experiments in the absence, and in others, exclusively in the presence of METH. From a comparison of experimental conditions under which various cell types showed unimpaired growth with conditions that enable a two- to threefold increase of enzyme activity, it may be concluded that this enzyme activity increase was a critical determinant of unimpaired growth.

The increase of mTHF:HOMmTase activity due to METH removal from the medium can be completely blocked by puromycin (*3*). From our findings on the protein synthesis response to the substitution of METH by HOM, it is evident that impairment of protein synthesis in L 5178Y, REF-S, and, in certain experiments, in HeLa cells could interfere with an increase of mTHF:HOMmTase activity and with the formation of METH in sufficient amounts to fulfill the requirement of these cells for this amino acid. Since this kind of protein synthesis response paralleled the type of response to METH-starvation, we conclude that differences in the sensitivity of protein synthesis to METH-starvation could account for differences in cell growth and survival on HOM.

These findings do not explain the cause or causes of the observed differences in the sensitivity of protein synthesis to METH-starvation. Protein synthesis does not reach its maximum rate until a certain intracellular concentration of amino acids is reached (*19*). As shown by Eagle et al. (*20*), the concentration of amino acids varies with the extracellular amino acid level and also with the specific acid and cell line. METH is not only an essential amino acid for protein formation, but it is also required for methylation of DNA, RNA, and proteins. In the absence of exogenous METH, complete ribosomes are not formed as a consequence of a lack of methyl groups required for ribosome synthesis from newly made 45 S precursor RNA (*21*, *22*). Different rates of protein synthesis shutdown in different cell lines could then result either from different rates of METH depletion or from variability in the rate of disappearance of methyl groups required for the initiation of protein synthesis.

HeLa cells showed varied responses to METH-depletion or METH-substitution. Since our experimental procedures were reproducible and since we can exclude the possibility of contamination of HeLa cells with some other cells in the course of passaging, the simplest explanation is that the cultures contained subpopulations differing in their metabolic features.

Preferential selection or overgrowth of one or another subpopulation at the time of the experiment could account for the observed variations. It has been reported that metastatic ability and tumorigenicity of HEp-3 cells (*23*) disappear during prolonged passage in culture. If this were true of HeLa cells and some other tumor derived-cells maintained in tissue culture for long periods of time, then the conclusions of Kreis and Goodenow (*8*) on the impossibility of general discrimination between benign and neoplastic cells on the ground of their METH requirement should be revised.

DNA Distribution in Human Colon Carcinomas and Its Relationship to Clinical Behavior[1,2]

R. C. Wolley, *Ph.D.*,[3,4] **K. Schreiber**, *M.D.*,[3] **L. G. Koss**, *M.D.*,[3,5] **M. Karas**, *M.D.*,[3] *and* **A. Sherman**, *M.S.*[3]

ABSTRACT—Striking differences in outcome of surgically treated colon adenocarcinomas were observed in 33 patients according to the DNA distribution patterns in tumor nuclei, measured by flow cytometry. As discussed and defined in the text and confirmed by appropriate control studies, the tumors were classified into 2 groups: predominantly diploid (20 tumors) and predominantly nondiploid (13 tumors). During the follow-up period of 3–5 years, 12 of the 13 patients with "nondiploid" tumors died of disease within 4–34 months, and the 1 patient still alive after 59 months has extensive metastases. Only 6 of the 20 patients with "diploid" tumors died of disease, sometimes after a slow, protracted clinical course. There were 14 patients with no evidence of disease for periods ranging from 30 to 60 months; 1 of these patients died of other causes. Histologic grading and Dukes' staging appeared to play a relatively limited role in the outcome, although lymph node metastases and vascular invasion were more often observed in the nondiploid tumors. These observations suggest that the determination of DNA distribution in colon carcinomas may prove to be of prognostic value.—JNCI 1982; 69:15–22.

The determination of nuclear DNA content, hence, in the broader sense, ploidy of large numbers of cells, has been facilitated by flow cytometry (*1–3*). This method is based on rapid measurements of fluorescence of specific dyes that bind stoichiometrically to double-stranded DNA. To perform the measurements accurately and avoid errors due to cell fragmentation and clumping, one must prepare a suspension of single cells; these cells must be stained with pure dyes of documented value and examined with an instrument with an appropriate wavelength.

In reference to solid epithelial human tumors, there are several significant problems with this approach. Because the cells in such tumors are bound to each other by desmosomes and other types of cell junctions (*4*), the preparation of a monocellular cell suspension must rely either on mechanical shearing of tumor fragments or on the use of proteolytic enzymes or on a combination of the two methods (*5, 6*). All of these agents and procedures cause varying degrees of damage to the cells (*7*). An alternate approach to the question of DNA distribution in human tumors is stripping the nuclei of their cytoplasm (*8, 9*). A suspension of intact, cleanly isolated nuclei obviates clumping that is commonly present in suspensions of cells derived from solid tumors. It is evident that the method used for nuclear isolation must be shown to preserve the DNA content in control studies.

Regardless of the method of preparation, samples of human solid tumors will contain a variable proportion of benign cells derived from blood vessels or connective tissue as well as an admixture of inflammatory cells. The DNA content alone is not sufficient for identification of such cells and for determination of their impact on the results of DNA measurements in tumors. For this reason, other control studies are necessary. The most secure way for one to determine the identity of cells or nuclei is based on morphologic criteria in smears (*10*). Such preparations may be stained by the Feulgen method. The measurement of the density of the Feulgen stain by means of a cytophotometer in a statistically valid sample gives rise to accurate histograms of the DNA distribution in a population of cells (*11*). Unfortunately, the time required for such studies is exceedingly long; thus the method does not lend itself to rapid determinations of clinical value. However, the method may be used on selected samples for the control of data obtained by flow cytometry.

In this paper we report a prospective study on the significance of the DNA distribution, determined by flow cytometry, in nuclei isolated from 33 colon carcinomas and appropriate controls. The method of preparation of the material and the resulting DNA distributions were controlled by the approaches described below. The DNA distributions of the tumors were compared with histologic grading and pathologic staging, and their prognostic value was judged by 3–5 years' follow-up of the patients.

MATERIALS AND METHODS

Samples.—In 1976 and 1977, samples of tissues were obtained from 33 fresh surgical resection specimens of colon carcinoma. Portions of grossly nonnecrotic tissue weighing approximately 2 g each were excised from tumors. Samples of colon epithelium of similar weight, taken from the margin of the surgical specimen showing no gross or histologic abnormalities, were used as controls. The benign epithelium was carefully separated from the muscle by a razor blade.

Preparation of suspension of nuclei.—Nuclei were isolated with the use of citrate buffer as previously described (*9*). The tissue samples were finely minced with scissors, incubated in a homogenization flask with 50 ml of CASC at room temperature for 30 minutes with constant agitation with the use of a magnetic stirrer, and then homogenized for 4 minutes with the use of a VirTis tissue homogenizer (setting #7).

ABBREVIATIONS USED: AO=acridine orange; CASC=0.09 *M* citric acid and 0.01 *M* sodium citrate; OD=optical density; PI=propidium iodide; TKM=0.05 *M* Tris, 0.02 *M* KCl, and 0.005 *M* $MgCl_2$ at pH 7.2.

This homogenate was cooled and filtered through eight layers of gauze for removal of any remaining tissue fragments, and the filtrate was centrifuged at 220×g for 10 minutes. The crude sediment containing nuclei was washed twice by resuspension in cold CASC, followed by centrifugation. The resulting suspension of nuclei was kept at 4°C until used. Aliquots of this nuclear suspension were checked by microscopic examination with the use of phase contrast and, after Papanicolaou staining, bright-field microscopy. Without exception, the preparations revealed well-preserved nuclei with only occasional wisps of cytoplasm attached. The nuclei to be analyzed by flow cytometry were washed several times in TKM, counted, and diluted to a concentration of 2×10^5/ml.

Normal human lymphocytes.—Normal, unstimulated human lymphocytes were used for control of staining and instrument adjustment and calibration. The lymphocytes were isolated from samples of peripheral blood from normal blood donors. Citrated blood, 1 ml, was diluted with 3 ml of normal saline and layered on 10 ml of Ficoll-Hypaque (Ortho Diagnostics, Raritan, N.J.) in a 15-ml centrifuge tube. The sample was centrifuged for 30 minutes at 400×*g*. The top cell band, consisting of approximately 90% lymphocytes, was removed with a Pasteur pipette and washed twice in phosphate buffer (pH 7.2) by centrifugation for 10 minutes at 220×*g*. The lymphocytes were either used immediately or frozen in phosphate buffer with 1% sucrose added for future use.

Staining.—Aliquots of nuclei isolated from all 33 tumor and benign control specimens were stained with the metachromatic dye AO (Sigma Chemical Co., St. Louis, Mo.) purified by the method of Zanker (*12*). One milliliter of AO solution (8.5×10^{-6} g/ml in TKM) was mixed with 1 ml of TKM containing 2×10^5 nuclei and allowed to equilibrate for 5 minutes (*13*). Measurements of green fluorescence at a wavelength of 530 nm corresponding to double-stranded DNA content (*14*) were made within 10 minutes of staining. During the latter part of this study, aliquots of 11 tumors and benign samples were also stained with PI (Calbiochem-Behring Corp., La Jolla, Calif.). Nuclei (1×10^5) in TKM were centrifuged for 10 minutes at 220×*g* and then resuspended in 1 ml of 0.1% sodium citrate containing 0.05 mg PI/ml (*15*). The suspensions of nuclei in PI were allowed to stand for 15 minutes at 4°C, and the DNA distributions were determined by measurement of the intensity of red fluorescence at 600 nm.

The DNA histograms generated by the two fluorochromes were compared and were in most instances identical. The small differences in the histograms that occurred in some cases were attributed to different aliquots of the nuclear samples used in these studies. In no case was the interpretation of the basic DNA distribution patterns affected by the choice of fluorochrome.

Measurements of fluorescence.—All counts and fluorescence measurements were made with the use of a Cytofluorograf system consisting of a Cytograf model 6300A, Cytofluorograf model 4802A, and a Multichannel Distribution Analyzer model 2100 (Ortho Instruments, Westwood, Mass.). After being stained as described, the nuclei were resuspended by being syringed twice with the use of a disposable tuberculin syringe fitted with a 25-gauge needle, and then they were analyzed immediately. We have found that this procedure results in a monodispersed sample, effectively disrupting any possible aggregates of nuclei that may form during centrifugation and staining (*16*). Before use with colon nuclei, the adjustment of the instrument and the quality of the batch of stains to be used were checked by generation of a DNA histogram of unstimulated lymphocytes. With an appropriate instrument setting and adequate stain, a histogram with a tight peak in the diploid range was generated.

The measurements of the nuclei of colon origin were conducted as follows: For each sample the benign control was studied first. Fluorescence intensity and light scatter were measured simultaneously. Light scatter provided information on the size of the particles and allowed us to exclude from the DNA histogram most of the debris, identified as small particles of lower fluorescence intensity than the diploid nuclei. It must be assumed that in every histogram some debris could not be differentiated from isolated nuclei. We analyzed each tumor immediately after its benign control had been analyzed without changing the setting of the instrument. We determined the reproducibility of results by generating, for each sample, a minimum of three histograms with AO and three with PI, when used. Each histogram was based on the measurement of 10^4 nuclei. Results were recorded as 100-channel histograms of fluorescence (text-fig. 1).

Control studies.—DNA content of isolated nuclei: To determine whether the steps used in nuclear isolation affected the DNA content of the sample, we compared the DNA content of two aliquots of the same tumor by the method of Savitzky and Stand (*13*).[6] In one aliquot (0.84 g in wet wt), the DNA was determined directly in the tissue. From the other tissue aliquot (0.86 g in wet wt), the nuclei were isolated as described, and their DNA content was determined. The DNA content, calculated per gram of wet tissue, was 11.6 mg for the whole tissue and 14.4 mg for the isolated nuclei. Thus the DNA content of the nuclei was not reduced by the citrate buffer isolation method.

Cytophotometry of Feulgen-stained samples.—After completion of the study of the 33 original tumors and controls that comprise this report, it became apparent that yet another method of determining the accuracy of the flow cytometric results was desirable. For this reason 2 additional colon tumors and benign controls were studied by flow cytometry and by measurement of Feulgen absorption. These flow cytometric histograms were generated on a recently acquired minicomputer (MINC 11; Digital Equipment Corp., Maynard, Mass.) interfaced with the Cytofluorograf. Smears of aliquots of nuclei isolated from the 2 colon tumors and their controls were fixed in 2% buffered formaldehyde for 12 hours and stained with Feulgen (*11*). The DNA content of 200 sequential nuclei from each of the samples was determined by quantitation of Feulgen absorption with the use of a high-resolution photometric system consisting of a Zeiss Universal Scanning microphotometer on line with a PDP-12 computer (*17*). The nuclei were scanned with a stepsize of 0.5 μm at a wavelength of 560 nm. Each nucleus was photographed at the time of scanning to facilitate subsequent identification. The raw data were measurements of the light transmission through a 0.8-μm effective aperture in the object plane. After the data were rescaled so that the minimum transmission in the background was assigned the value of 190, the OD was then calculated from the Beer-Lambert Law; OD = $-\log (t/t_0)$, where t is the local transmission value and t_0 is the background transmission value taken to be 200. This OD value was scaled up by a factor of 100 for convenience, since the values were then represented as integers.

---

[6] We thank Dr. Simon Neubort, Department of Radiology (Radiobiology), Albert Einstein College of Medicine, for his contribution to this study.

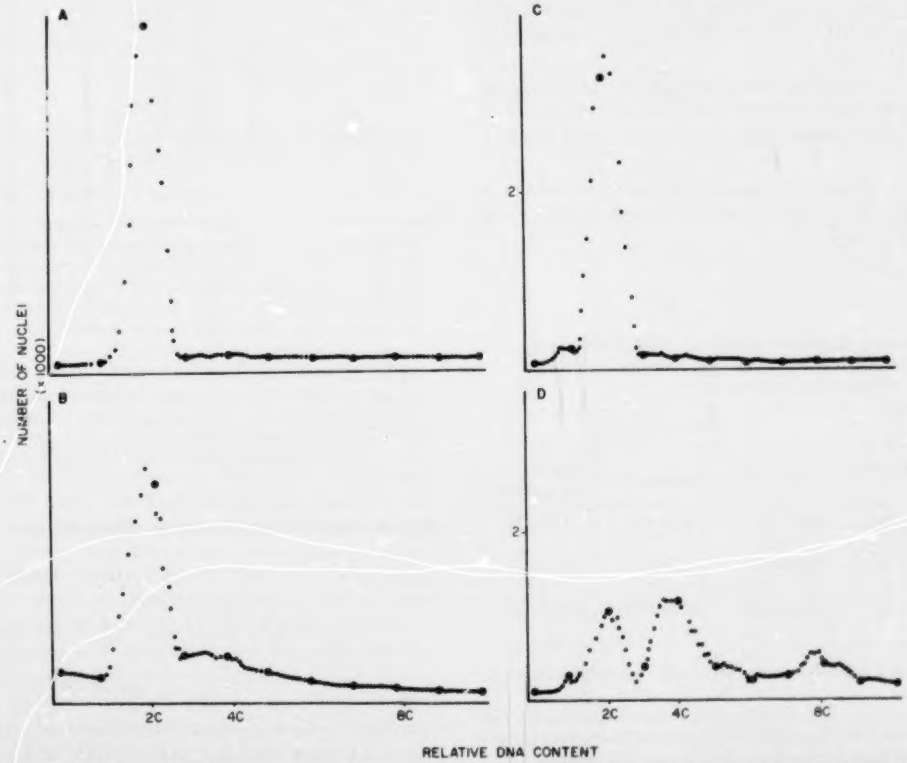
After the transformation of the image from transmission to OD values, the area and integrated OD of the nucleus were calculated and stored. After an entire sample had been run, OD distributions, which correspond to DNA distributions, were collected and plotted. All of the data were visually correlated with individual nuclei that were classified as either of benign or of malignant type on the basis of well-defined morphologic characterization of the nucleus (such as shape, chromatin pattern, size, and number of nucleoli) routinely used to distinguish between normal and malignant cells (*10*). The histograms of the control benign samples were based on the 200 nuclei (text-figs. 2, 3). Two histograms of the malignant samples were obtained: the first based on the 200 nuclei (text-figs. 2B, 3B) and the second after exclusion of morphologically benign or questionable nuclei (text-fig. 3C).

Pathologic evaluation and follow-up of patients.—Histologic grade, the presence of vascular invasion, lymph node metastases, and Dukes' stage were determined for each tumor. The modified Dukes' system (*18*) used classified tumors confined to mucosa and submucosa as A, invading muscularis as B, invading periserosal fat with or without metastasis to regional lymph nodes as C, and presenting distant metastases as D. The results of follow-up of the patients were obtained from the Tumor Registry at Montefiore Hospital and Medical Center by direct communication with individual physicians and, in some cases, by postmortem examination.

RESULTS

Flow Cytometry

The histograms of the DNA distribution of the 33 control samples of nuclei isolated from benign colon epithelium were typical of those of a cycling, nonsynchronized cell population (text-figs. 1A, 1C). The large peak in the diploid



TEXT-FIGURE 1.—Histograms based on the measurement of the fluorescence intensity of 10,000 PI-stained nuclei. A and C: Typical histograms for nuclei obtained from benign colon epithelium showing a diploid cell population. Most of the nuclei represent cells isolated during the G_0 and G_1 phases of the cycle, with a small S-phase and G_2 phase group. A is the control for B, and C is the control for D. B: Histogram obtained from a grade II, Dukes' B-tumor is typical of histograms on patients who showed no evidence of disease 3–5 yr after surgery. Bulk of the nuclear sample is in the diploid region, although a secondary near-triploid population of nuclei is present. D: Histogram of a grade II Dukes' C-tumor removed from a patient who developed recurrent disease. There are three distinct peaks: one in the diploid region, one dominant peak in the tetraploid region, and one in the octaploid region. In the absence of a dominant peak in the diploid region, the tumor was classified as nondiploid.

range represented cells in G_0 and G_1 stages of the cell cycle. A small peak formed by nuclei with twice the DNA content (tetraploid or 4C) corresponded to cells in G_2, and the nuclei with intermediate DNA content presumably corresponded to cells in S-phase. Table 1 shows that there was little variation among the benign samples.

The histograms of DNA distribution of the 33 tumor samples could be divided into 2 groups (table 1). In the first group composed of 20 samples, the overall histogram patterns were roughly similar to those obtained with the benign samples (text-fig. 1B). Most nuclei (mean of 86.4% ± SD of 6.4%) formed only one major peak centered around the 2C region of the histogram, while the remainder of the nuclei were distributed between 2C and 8C. The broad configuration of the principal peak clearly indicated that the DNA content was much more variable than that in the benign controls. This group of tumors was classed as "predominantly diploid" with the clear understanding that this term indicated an approximation of the DNA content and did not exclude the possibility that subpopulations of hypodiploid, hyperdiploid, or even triploid nuclei may also be present within the peak.

In the 13 remaining tumors, the proportion of nuclei in the 2C region was significantly smaller (mean of 37.9% ± SD of 15.5%). The tumor histograms displayed a variety of patterns forming major peaks in the 3C or 4C regions and even beyond (text-fig. 1D). These tumors were classified as "nondiploid."

Using Student's t-test, we determined that the difference in the proportion of diploid nuclei among the benign samples and the 2 tumor groups was statistically significant ($P < 0.001$).

No attempts were made to identify the stages of cell cycle in tumor cells. We believe that such attempts would have been highly speculative.

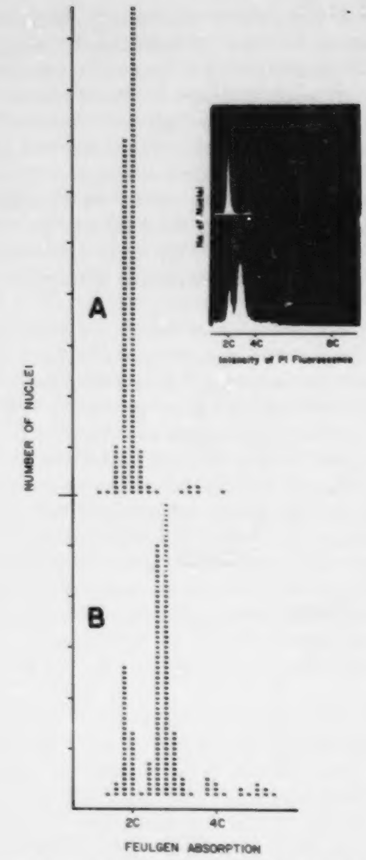
TABLE 1.—*Summary of DNA distribution data based on flow cytometry of 33 colon carcinomas and suitable controls, as described in text*[a]

Samples	No. of samples	Means ± SD, %		
		Region 2C	Region 3C	Region 4C and greater
Benign controls[b]	33	93.8±3.6	2.7±1.8	3.5±2.3
Tumors[c]				
Predominantly diploid	20	86.4±6.4	5.3±2.2	8.4±6.0
Predominantly nondiploid	13	37.9±15.5	36.6±29.5	25.9±18.7

[a] Each measurement of 10,000 nuclei was performed three times or more.

[b] Benign control samples had a DNA distribution characteristic of that of a cycling normal cell population, with most of the cells in the 2C region and a small proportion of cells in the 3C and 4C regions.

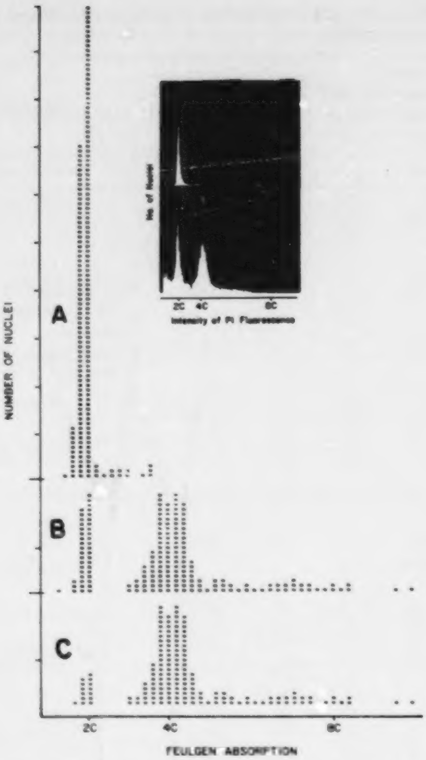
[c] On the basis of their DNA distributions, the colon carcinomas were divided into 2 groups: 1 group of 20 tumors with the majority of nuclei in the diploid range and the other group with a majority of nuclei in greater than the diploid range. The tumor nuclei in the diploid region did not form sharp peaks as seen in control samples but rather had a broad distribution of cells of similar, but not necessarily identical, DNA content.



TEXT-FIGURE 2.—Comparison of DNA histograms of nuclei determined by measurement of Feulgen absorption by high-resolution cytophotometry of 200 nuclei in a control sample of benign epithelium (A) and a corresponding colon carcinoma (B), with measurement of DNA content of 10,000 nuclei from each of the same samples by flow cytometry (*inset*). In spite of the differences in the numbers of nuclei measured, the histograms obtained by the two methods of DNA quantitation are very similar. Control sample shows a typical diploid cell population (A and *top inset*). Tumor shows two peaks: one in the diploid region and one in the triploid region. In this case all of the tumor nuclei studied by the Feulgen method were visually classified as malignant, indicating that a proportion of malignant cells were diploid in a tumor classified as nondiploid.

Measurements of Feulgen Absorption

The histograms of Feulgen absorption of the two control samples were nearly identical to those obtained by flow cytometry: Nearly all of the nuclei formed a single peak corresponding to the 2C value. The remaining nuclei with higher DNA content presumably represented replicating cells (cf. text-figs. 2A and 3A with text-figs. 1A and 1C and top insets). The Feulgen histograms of nuclei from the 2 tumor samples had a more variable DNA content, which indicated cell populations of variable ploidies, and were virtually identical with histograms generated by flow cytometry (cf. text-figs. 2B and 3B with bottom insets). By visual inspection of photographs taken of each nucleus in the Feulgen-stained smears, none of the nuclei in the control samples were classified as malignant. In the first tumor



TEXT-FIGURE 3.—Comparison of DNA histograms of nuclei derived from a benign control sample (A) and colon carcinoma (B and C) by the Feulgen method and by flow cytometry of the same samples (*inset*). Histogram B was based on 200 sequential nuclei derived from the tumor. A very similar distribution of DNA content is present in the tumor histogram generated by flow cytometry (*inset, bottom*). Tumor was classified as nondiploid. After visual elimination of morphologically benign or questionable nuclei, histogram C was constructed, which shows that the tumor contained a significant population of nuclei of malignant origin in the diploid region and in the tetraploid region.

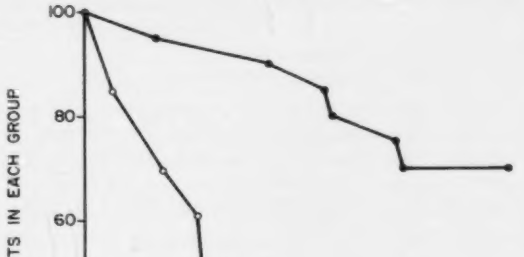
sample, all of the nuclei had malignant characteristics, regardless of DNA content. In the second tumor, benign and malignant nuclei were present. Those nuclei visually classified as benign or questionable were all diploid and were eliminated from the histogram shown in text-figure 3C, which is based only on nuclei *positively identified as malignant*. There was a proportion of nuclei with morphologic characteristics of cancer that fell within the diploid range. Furthermore, the basic configuration of the two histograms (text-figs. 3B, 3C) has remained similar, even after the elimination of presumably benign or questionable nuclei.

Pathologic and Clinical Data

Table 2 lists the principal clinical and pathologic data on the 33 patients studied. The tumors among these patients were divided into the 2 groups: predominantly diploid and predominantly nondiploid. Table 3 compares the flow cytometric classification of the colon tumors to conventional methods of tumor evaluation. Among the 20 patients in the diploid category, there were 2 tumors of grade I, 16 tumors of grade II, and 2 tumors of grade III. In the nondiploid tumor group there were 2 tumors of grade I, 7 tumors of grade II, and 4 tumors of grade III. There was evidence of lymph node metastases in 8 of 20 tumors in the diploid group and 10 of 13 tumors in the nondiploid group. Definite evidence of vascular invasion by tumor was observed in 4 of 20 diploid and 9 of 12 nondiploid tumors. Correlation with Dukes' classification showed that the diploid tumors were divided between Dukes' B- and C-classifications (7 and 10, respectively) with 1 tumor classified as Dukes' A and 2 as Dukes' D. Only 2 of the 13 nondiploid tumors were classified as Dukes' B with the other 11 classified as Dukes' C. Correlation of patient follow-up with the 2 tumor groups showed that 14 of the 20 patients with diploid tumors remained free of disease and 6 died of recurrent disease. Of the 13 patients with nondiploid tumors, all had recurrences of disease within 2 years and only 1 survived with metastatic disease beyond 3 years. The differences are reflected in the life-table analysis (text-fig. 4).

The patients in the nondiploid category, with one exception, died of disease within a short period of time, ranging from 4 to 34 months after surgery, with an average survival of 17.7 months. The sole survivor of 59 months has extensive liver metastases.

In the diploid group, 2 patients with known liver metastases at initial surgery survived 34 and 45 months, respectively. There were also 3 patients with lymph node metastases who remained free of disease, although 2 of them died of unrelated causes after 30–34 months of follow-up. The average survival time of the 5 patients who died of disease



TEXT-FIGURE 4.—Survival of patients with diploid tumors (●) and nondiploid tumors (○). At the end of 24 mo of follow-up, >90% of the patients with diploid tumors were alive, compared with <25% of patients with nondiploid tumors. After 5 yr of follow-up, 13 of the 20 patients (65%) with diploid tumors were alive with no evidence of disease (1 of them died of unrelated cause without evidence of disease); only 1 of the 13 patients in the nondiploid group (7.5%) was still alive with extensive metastases, 59 mo after surgery.

TABLE 2.—*Correlation between the DNA distribution of 33 colon carcinomas with clinical follow-up, histologic grading, lymph node metastases, vascular invasion, and Dukes' classification*[a]

Patient No.	Sex	Age, yr	Location and size of tumor	Grade	Vascular invasion	Lymph node metastases[b]	Dukes' stage	Follow-up in mo	Results[c]	Remarks[d]

[a] There was no significant correlation between histologic grade and DNA distribution except for the grade III tumors of which 4 of 6 were nondiploid. All of the patients with nondiploid tumors had either lymph node or vascular involvement, and all but 1 died of disease within <3 yr. Comparison of Dukes' staging with DNA distribution shows that the nondiploid tumors generally had a higher stage than the diploid tumors. Yet most patients with diploid patterns remained free of disease regardless of Dukes' stage. Furthermore, the progression of disease was very slow in some patients with diploid tumors (patients 11 and 14).

[b] No. of lymph nodes with cancer/total No. of lymph nodes found.

[c] NED=no evidence of disease. DOD=dead of disease. EOD=evidence of disease.

[d] FUra=patient treated with 5-fluorouracil.

TABLE 3.—*Summary of table 2 showing comparison of the flow cytometric classification of the colon tumors with conventional methods of tumor evaluation*[a]

Pathologic classification	Total No. of samples	Predominant ploidy	
		Diploid	Nondiploid
Dukes' classification			
A	1	1	0
B	9	7	2
C	21	10	11
D	2	2	0
Histologic grades			
I	4	2	2
II	23	16	7
III	6	2	4
Lymph node metastases	18	8	10
Vascular invasion	13	4	9

[a] For discussion, *see* table 2, footnote *a*.

was 31.8 months, nearly twice as long as that for the nondiploid group.

DISCUSSION

Behavior patterns, hence prognosis of carcinoma of the colon, one of the most frequent malignant tumors observed today, has been studied by Dukes who has introduced the commonly accepted system of staging (*19*). This system provided broad prognostic statistical guidelines based on gross findings and histologic evidence. Histologic grading, also proposed by Dukes (*20*), is a highly subjective exercise that reflects the pathologist's training, competence, and ability.

The purpose of the research described in this paper is to base the prognosis of colon cancer on objective, machine-generated criteria. Initial attempts to determine the prognostic value of ploidy of various human cancers were made with the use of Feulgen stain and chromosome counts (*21–23*). In reference to carcinomas of the uterine cervix and the endometrium (*24*) and the breast (*25*), Atkin concluded that tumors of predominantly diploid pattern generally had a better prognosis than aneuploid neoplasm. Since the development of flow cytometry, the ploidies of a variety of solid human tumors have been determined (*26–33*). These studies have confirmed the abnormalities in DNA distribution in various forms of human cancer. However, because of insufficient length of follow-up, the prognostic significance of the flow cytometric observations has not been previously established (*34*).

Flow cytometry offers the advantage of a large data base to establish the ploidy of human cancer for purposes of diagnosis and prognosis. Unfortunately, the preparation of cell suspensions by mechanical shearing or proteolytic enzymes often results in cell destruction or insufficient dispersion of cells (*7*). In the case of colon tissues, it proved impossible to obtain a suspension of intact, single cells. For this reason, this research was based on the study of isolated nuclei, as also used by Vindeløv et al. (*32*). The main disadvantage of this approach is the inability to study metabolic events in the cytoplasm. The method of nuclear isolation described in this study is a modification of that used by Skerrow and Matoltsy (*35*) for isolation of desmosomes from epidermis. Fortuitously, this modified method results in a suspension of intact nuclei of remarkable purity and has been extensively tested on tissues and cells from the uterine cervix, lung, colon, and liver (*9*). The comparison of the DNA content of the isolated nuclei with intact tissues, described in this paper, proved that the DNA recovery is high. Nuclei prepared by this method do not have to be fixed or analyzed immediately because the low pH of the solution used for nuclear isolation inhibits the action of endonucleases (*36*). We have found this method reproducible and reliable with a variety of tumors. Thus, if generally accepted, this method may prove to be a common denominator for the study of DNA content of various human and experimental neoplasms.

Flow cytometry has one more inherent weakness, i.e., the inability to identify in flow the nature of the particles generating the signals. Suspension of nuclei, even though derived from clearly cancerous tissue, may consist of an admixture of nuclei of benign cells, vascular connective tissue, and hematogenous origin. For this reason, a cytophotometric control study of Feulgen-stained nuclei was performed. The fact that the DNA histograms generated by flow cytometry and by Feulgen absorption of epithelial nuclei were remarkably similar (text-figs. 2, 3) suggests that nuclei of nonepithelial cells had little if any effect on the results. With the use of visual criteria, this study also confirms the presence of malignant cell nuclei within the diploid range (text-figs. 2B, 3C). This possibility has been suggested by others who found that the large population of diploid nuclei in colon tumors cannot be explained by contamination with normal cells (*37, 38*).

Interpretation of DNA histograms generated by flow cytometry for a cycling diploid cell population, such as stimulated lymphocytes or cells in tissue culture, is relatively simple, and several methods of calculating the proportions of cells in different stages of the cell cycle are available (*39, 40*). However, determining the cell cycle stages in a complex cell population of unknown ploidy, such as one derived from human cancer, is much more difficult, if not impossible, with the technology available to us in 1976 and 1977 when this study was performed. The state of the cell cycle can be surmised or guessed for such histograms as shown in text-figures 1–3 only if one assumes that the ploidy of the cells is known and constant and all the cells are cycling normally.

For this reason, the tumors were assessed in reference to DNA content of nuclei, and the possible implications of cell dynamics or ploidy were disregarded pending further research. Fortuitously, the colon tumors had two predominant DNA distribution patterns: one predominantly diploid and the other nondiploid as already defined. Since the inception of this study, others have reported similar observations without indicating their possible prognostic value (*37, 38*). It appears from our follow-up data that these 2 groups of tumors have a strikingly different behavior pattern. The diploid group appears to be much less aggressive even in the presence of known metastases. The nondiploid tumors lead to rapid dissemination of the disease and patients' death within a short period of time, which strongly suggests a correlation between ploidy of colon tumors and prognosis as has been noted for some other human tumors (*24, 25*). Thus the results suggest that biologic factors of either tumor aggressiveness or patients' resistance to disease are somehow reflected in the DNA distributions. Obviously, the results of this report based on the small group of patients must be confirmed by additional data.

ABSTRACT—The clinical course, human chorionic gonadotropin (HCG) levels, and serial circulating immune complex (CIC) levels in 21 patients with gestational trophoblastic neoplasia (GTN) were correlated for the evaluation of the relationship between CIC levels and trophoblastic tumor burden. CIC levels were normal in 18 of 21 patients at the time of presentation, and 2 of the 3 patients who presented with elevated CIC levels had significant comorbid disease (toxemia and hepatitis). Nine patients were followed into gonadotropin remission, and all 9 developed an increase in CIC levels at the time of remission. It was concluded that CIC, at least as measured by two antigen-nonspecific techniques, is generally not elevated at initial presentation in the patient with GTN; this lack of an elevation is probably due to marked tumor antigen excess. Thus the in vivo importance of CIC as a "blocker" of host antitumor response at this stage is doubtful. After effective treatment as HCG levels return to normal, the demonstrated elevation in serial levels of CIC may reflect a return of adequate host immune response at a time of minimal tumor burden.—JNCI 1982; 69:23–26.

We and other investigators have reported increased levels of CIC in patients with cancer (*1–3*). Clinical monitoring of CIC has been proposed as a marker for tumor prognosis, response to therapy, and recurrence (*4–6*). Nevertheless, the clinical usefulness of antigen-nonspecific immune complex assays in a variety of patients with different tumor diagnoses continues to be disputed (*7*). We have recently selected a group of patients with GTN to assess the potential clinical value of serial CIC monitoring. We believe that these patients would most likely reflect clinically significant CIC changes, because their tumors are uniquely responsive to chemotherapy (even when presenting with widespread metastases) (*8*), because they can be followed to complete remission in a relatively short period of time, and because GTN regularly and predictably secretes HCG that can be used as a sensitive and specific quantitation of trophoblastic tumor (*9*).

The current study was undertaken for assessment of CIC levels in patients with HM with the use of two antigen-nonspecific CIC assay techniques: the PEG turbidity assay and the C1q binding assay. Serial levels of CIC and HCG were measured in patients with molar pregnancy for determination of the relationship between CIC and trophoblastic tumor burden.

MATERIALS AND METHODS

Twenty-one patients who presented to the New England Trophoblastic Disease Center from January 1980 to March 1981 with histologically confirmed HM were included in this study. The mean age of these patients was 25.6 years with a range of 17–38 years. Thirteen patients presented with molar pregnancy in situ, and 8 were referred with persistent postevacuation trophoblastic disease.

All serum samples were obtained from the patients in the morning after an overnight fast and used immediately for the HCG assay or stored at −70°C for subsequent CIC determinations. Serial samples on individual patients for the two antigen-nonspecific CIC assays were thawed only once with parallel assays performed on the same day.

Serum HCG levels were determined by the beta subunit radioimmunoassay method originally described by Vaitukaitis and associates (*10*) and modified by Kosasa and coworkers (*11*). This assay is specific for HCG and has a sensitivity of 10 mIU/ml. Patients were considered in remission after three consecutive normal weekly HCG levels (*8*).

Two antigen-nonspecific CIC assays were performed. C1q binding of CIC was determined by the method of Nydegger et al. (*12*), modified by Zubler et al. (*13*). Radiolabeled C1q was added to EDTA-treated serum samples, and bound C1q was then precipitated with PEG. The upper limit of normal for this assay in our laboratory is 23 µg aggregated human globulin equivalents per milliliter (*14*). The PEG turbidity assay for CIC has been previously reported in detail from our laboratory (*1, 15*). We have recently modified this PEG turbidity technique by using a final serum dilution of 1:10 in borate buffer (0.1 *M*, pH 8.4) containing PEG 6000 at a final concentration of 3.75% (wt/vol). After 2 hours of

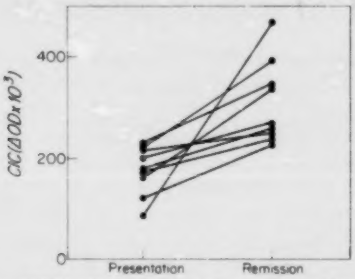
incubation at 20°C, samples are read on a Perkin-Elmer double-beam spectrophotometer (Perkin-Elmer Corp., Oak Brook, Ill.). Increase in turbidity due to insolubilization of CIC by PEG is reported as ΔOD units × 10^{-3}. Values greater than 280 represented two standard deviations from our pooled normal human serum controls (*1*).

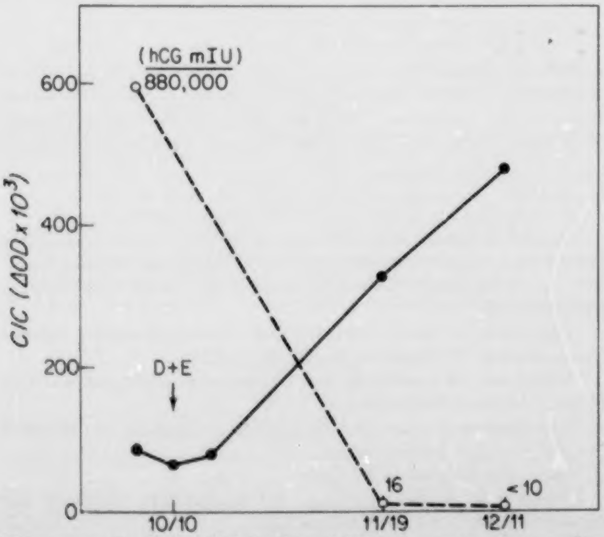
RESULTS

CIC levels by both the PEG and the C1q binding assays were normal in 18 of 21 GTN patients at the time of their presentation for treatment. The median initial CIC value was 203 ΔOD U × 10^{-3}. Two of 3 patients who presented with elevated CIC levels in the PEG assay also had elevations by C1q binding. These 2 patients had significant comorbid disease at time of presentation—1 with toxemia and the other with hepatitis.

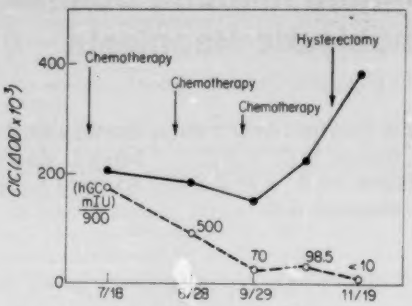
Serial CIC and HCG levels were measured on a median of five samples per patient (range, 2–11). Nine patients were followed into gonadotropin remission, and all 9 demonstrated an increase in their serial CIC levels by the PEG turbidity assay at the time of remission (text-fig. 1). The clinical, gonadotropin, and PEG–CIC course in a patient cured by molar evacuation is summarized in text-figure 2.



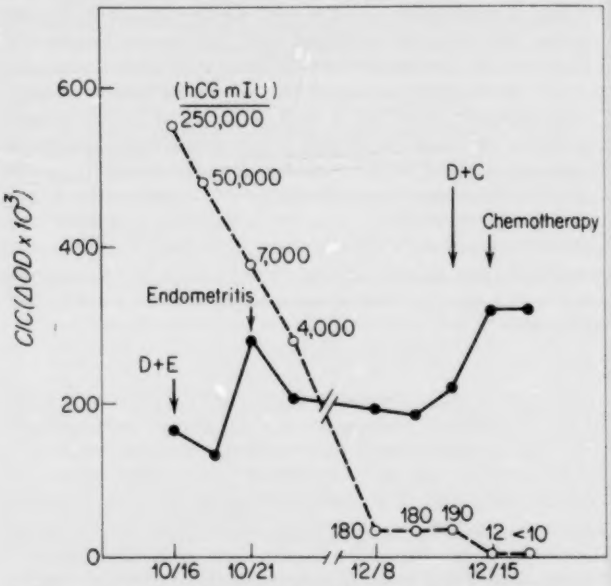
TEXT-FIGURE 1.—CIC levels at time of presentation and remission for the 9 patients entering gonadotropin remission.



TEXT-FIGURE 2.—Serial HCG (hCG) and CIC values in a patient cured by molar evacuation.

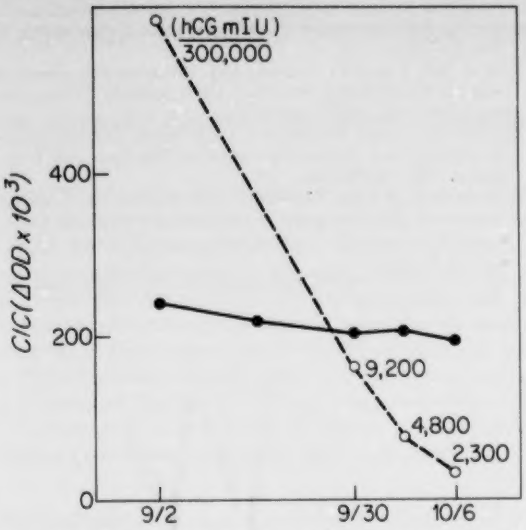


TEXT-FIGURE 3.—Serial HCG (hCG) and CIC values in a patient requiring multiple courses of chemotherapy and hysterectomy to induce remission.



TEXT-FIGURE 4.—Serial HCG (hCG) and CIC values in a patient who was sustaining intercurrent infection and was eventually cured by additional surgery and chemotherapy.

Elevations in serial CIC levels were observed only in patients at the time of gonadotropin remission or in patients with comorbid disease. Text-figure 3 depicts the course of a patient with nonmetastatic trophoblastic disease who required chemotherapy and eventual hysterectomy for induction of tumor remission. Despite an early dramatic fall in HCG level, CIC did not rise until a minimal tumor burden was achieved as indicated by HCG values approaching normal. During episodes of comorbid illness, CIC elevations (presumably not related to changes in tumor burden) were observed. Text-figure 4 demonstrates the effect of infection on CIC levels in a patient who developed endometritis during treatment. Despite dramatic reduction in tumor bulk, quantitated by HCG decrease, patients who did not enter gonadotropin remission did not develop increases in serial CIC values. Text-figure 5 summarizes the course of such a patient who was initially treated by molar evacuation and then chemotherapy for persistent trophoblastic disease.



TEXT-FIGURE 5.—Serial HCG (hCG) and CIC values in a patient who, following molar evacuation, had not yet entered remission.

DISCUSSION

Molar pregnancy is an excellent clinical model for assessment of the potential relationship between CIC and tumor burden. The amount of viable trophoblastic tumor is sensitively and specifically quantitated by the serum level of HCG. Because trophoblastic tumors are exquisitely responsive to therapy, patients may be followed from presentation with bulk disease until they achieve complete gonadotropin remission in a relatively short period of time. In addition, patients with molar gestation are generally young and free of significant comorbid disease.

In this study, 18 of 21 patients with molar pregnancy had normal CIC levels at presentation as measured by two antigen-nonspecific assays. Two of the 3 patients who presented with elevated CIC levels had a significant comorbid disease—toxemia and hepatitis. Nine patients were followed until they achieved gonadotropin remission, and all 9 developed elevation of serial CIC levels at the time of documented remission. In all of the other patients, CIC values were elevated only when comorbid disease such as endometritis was present.

Three general problems must be considered when CIC is evaluated in any patient with neoplastic disease. First, CIC levels must be measured serially in individual patients who have a well-defined tumor course. Variation in the kinetics of CIC formation, elimination, and detectability may lead to a wide range of "normal" values. Attempts to define arbitrary normal and abnormal CIC values, in contrast to using the patient as her own control in serial studies, will bias against finding any significant biologic effect. Thus, although all of the patients developed increased levels of serial CIC at the time of gonadotropin remission, individual remission CIC values were above our own normal range in only 4 of the cured patients. The elevations in CIC in the other 5 patients would not have been detectable with the use of single serum samples, regardless of the antigen-nonspecific assay used.

Second, comorbid disease must be carefully considered when CIC data are analyzed. Elevated CIC levels were presumably due to comorbid disease in 3 patients—2 at presentation and 1 during the course of therapy.

Third, the measurement of CIC with any antigen-nonspecific assay will depend on the capability of the particular methodology applied. In this group of patients, the PEG turbidity assay detected elevated CIC levels more frequently than did the C1q binding assay. Although the PEG turbidity assay can detect CIC containing all immunoglobulin classes, C1q binding can only measure CIC containing immunoglobulin capable of binding complement (*1*).

It is interesting to speculate why patients with molar pregnancies develop elevated CIC levels only at the time they enter gonadotropin remission. Since HM is unique among human tumors in possessing a full complement of paternal chromosomes (*16*), these tumors may appropriately be regarded as allogeneic tissue and should provide a major antigenic challenge to the host immune system. At the time of presentation, patients may have such a large tumor burden that circulating antigen is in great excess. In previous work, we have shown that the PEG-CIC assay is not capable of accurately quantitating model complexes in extremes of antigen excess (*11*). The reduced tumor burden in these patients near the time of remission may provide a more suitable antigen:antibody ratio for CIC formation and detection, due either to a decrease in circulating antigen load by effective therapy or to an increase in host antibody production after a temporary period of immune incompetence.

The increased levels of CIC at the time of gonadotropin remission in these patients may signify a vigorous host immune response at a time of minimal tumor burden. Further investigation is warranted to isolate and analyze the contents of these immune complexes and to delineate the serial course of CIC values in cured patients followed longer after gonadotropin remission.

Decrease of Tumor Growth in Mice After Intravenous Thymosin-Treated Bone Marrow Cell Injection[1,2]

Didier Cupissol,[3] **Augustin Rey,**[3] **Allan L. Goldstein,**[4] *and* **Bernard Serrou**[3,5]

ABSTRACT—The effect of iv injection in C57BL/6 mice of 3×10^7 bone marrow cells preincubated in either thymosin fraction V or thymosin α-1 was evaluated on the growth of a 3-methylcholanthrene-induced transplantable tumor in a syngeneic system. The effect was then compared to that elicited by theophylline or levamisole, which both demonstrated thymosin-like action in vitro. The results showed significantly retarded tumor growth ($P<0.001$) and prolonged survival time ($P<0.001$) when thymosin fraction V was used. The same results were obtained with thymosin α-1 with use of the same protocol but only one-twentieth of the concentration of fraction V. Theophylline and levamisole demonstrated no antitumor effect.—JNCI 1982; 69:27–31.

Recent studies suggest the presence of an immune imbalance in both tumor-bearing animals (*1*) and in cancer patients (*2, 3*). This imbalance is characterized by an increased level of immune complexes (*4, 5*) and by the presence of suppressor cells (*6–11*). Two phases are distinguishable in this imbalance: an early phase after tumor implantation characterized by the presence of tumor-inhibiting lymphocytes and a later phase characterized by the presence of tumor-enhancing lymphocytes that possess in vitro cytotoxicity for target cells (*12*). Moreover, Small and Trainin (*13*) have shown that tumor-inhibiting sensitized lymphocytes are not observed when tumor-enhancing lymphocytes are present. The concept of immune balance still contains many unknowns with regard to its regulation of and action on lymphocyte differentiation and maturation (*3*). Among these unknowns are thymosin (*14*), thymic factor (*15*), factor thymique serique (FTS) (*16, 17*), and thymic humoral factor (THF) (*18*).

Ahmed et al. (*19*) and Goldstein et al. (*20, 21*) have shown that the thymic extract thymosin fraction V can elicit differentiation of bone marrow lymphocytes into T-lymphocytes. Thymosin fraction V includes thymosin α-1 and other subfractions involved in the differentiation and maturation of helper, cytotoxic, and suppressor cells (*19, 22, 23*). Recent experimental and clinical results suggest that substances such as thymosin can restore immune balance and simultaneously modulate the amplitude of the immune reaction and the suppressor activity (*10, 11, 23, 24*). Within this context, some investigators have shown that T-lymphocytes may facilitate growth of murine syngeneic tumors (*25*). The same phenomenon was observed for cells that were autosensitized in vitro beforehand (*26*). Since these lymphocytes arose from the thymic cortex and were identified as suppressor cells, they may be found to facilitate tumor growth (*25*).

Consequently, it seemed reasonable to evaluate the effect of a thymic factor, such as thymosin, on the modulation of tumor growth by T-lymphocytes. We confirmed the previous findings of Umiel and Trainin (*25*) who described a T-lymphocyte population that enhanced tumor growth. We found this population sensitive to both cortisone and irradiation (*10*). These lymphocytes lost their tumor growth-enhancing potential when they were preincubated in a thymic factor (*27*) other than thymosin and not only significantly reduced tumor growth but also reduced the number of pulmonary metastases. These results seemed sufficiently encouraging to warrant evaluation of the thymosin effect on bone marrow cells injected into mice with MCA-induced tumors. We chose the bone marrow cell model because it is directly applicable to the situation in cancer patients and because the known regulatory role of bone marrow and null cells (*28, 29*). In addition, it was of interest to compare these results with those obtained with levamisole and theophylline (*30–32*) which show similar effects in vitro on lymphocyte differentiation as those observed for thymosin (*11*).

Our results show that bone marrow cells from normal syngeneic mice do not stimulate tumor growth and that bone marrow cells preincubated with thymosin significantly inhibit local syngeneic tumor growth.

MATERIALS AND METHODS

Tumor system.—The animals used were 12-week-old C57BL/6 male mice. The left hindlimb was injected with 2×10^6 viable tumor cells from an MCA-induced transplantable tumor maintained in our laboratory. This tumor is lethal at 31±1.7 days, is weakly immunogenic in vitro, and is unable to induce T-cell cytotoxicity, killer, or NK activities (*33*). However, in vivo immunization can be induced by either amputation 14 days after tumor implantation or ip injection of irradiated tumor cells.

We evaluated the following criteria: tumor weight, tumor volume, and mean survival time. Tumor weight and volume were evaluated on days 7, 14, 21, and 28 after iv injection of bone marrow cells. We injected a large number of viable tumor cells (2×10^6) to parallel the human situation where the tumor mass is often substantial at the time of diagnosis.

ABBREVIATIONS USED: A-RFC=autorosette-forming cells. MCA=3-methylcholanthrene; NK=natural killer.

[g] $P<0.05$ for the group comparisons: 1 vs. 3, 4, 5, and 6; 2 vs. 4, 5, and 6; 3 vs. 4, 5, and 6; 4 vs. 5 and 6.

Bone marrow cells.—We obtained bone marrow from 12-week-old normal syngeneic mice by flushing the femur with RPMI-1640 medium (Gibco-Biocult, Glasgow, Scotland). Cells were then counted, viability was evaluated by trypan blue exclusion, and 3×10^7 bone marrow cells in 0.2 ml RPMI-1640 were injected iv either on the day of tumor implantation or 10 days after tumor implantation.

Drugs.—We used concentrations of 400 μg/ml/2×10^6 bone marrow cells for thymosin fraction V (lot C 100496) and 20 μg/ml/10^6 cells for pure thymosin α-1 (lot 160486). Theophylline (Bruneau Pharmaceutical Co., Paris, France) was employed at 200 μg/ml/2×10^6 cells and levamisole (Specia Pharmaceutical Co., Paris, France) at 200 μg/ml/2×10^6 cells. For all drugs, incubation time was 1 hour at 37°C. The dose retained for experimentation was that which in our experience yielded the maximum increase in vitro of A-RFC in the immunodepressed patient (A-RFC, <15%) with advanced solid tumor (*34*, *35*).

Experimental groups.—Each group contained 30 mice. Each experiment was repeated four times. In the first part of the study, experimental groups received normal syngeneic bone marrow cells pretreated with different drugs and injected iv on the day of tumor implantation. In the second part of the study, experimental groups received normal syngeneic bone marrow cells pretreated with the same drugs at the same concentrations as in the first part but injected iv 10 days after tumor implantation.

RESULTS

Experimental groups receiving normal syngeneic bone marrow cells pretreated with drugs and injected iv on the day of tumor implantation.—Animals given injections of 3×10^7 normal bone marrow cells (group 2) demonstrated no tumor growth inhibition (table 1). Tumor growth was similar to that of the control animals which did not receive bone marrow cells (group 1). On day 7, tumor weight and volume decreased significantly in animals given injections of thymosin fraction V- or thymosin α-1-preincubated bone marrow cells (groups 3 and 4) compared to animals that received untreated bone marrow cells (group 2). This difference persisted and became more accentuated on days 14 and 21.

Animals receiving bone marrow cells pretreated with levamisole or theophylline (groups 5 and 6) demonstrated

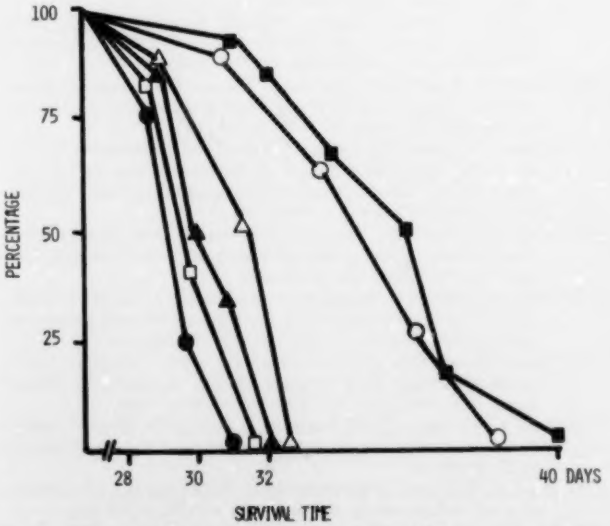
an enhancing effect (significant weight difference on day 7, then a slight difference on days 14, 21, or 28) compared to that seen in control group 2 and in the groups treated with the thymosin plus bone-marrow cells (groups 3 and 4; table 1).

We found significant differences in survival times in favor of animals in groups 3 and 4 compared with groups that received levamisole- or theophylline-pretreated cells (groups 5 and 6) (text-fig. 1). There was no significant difference in survival times between the groups receiving thymosin fraction V and thymosin α-1.



TEXT-FIGURE 2.—Thymosin-preincubated syngeneic bone marrow cells increase survival time in mice when injected iv 10 days after tumor implantation. ●, Controls; ▲, bone marrow cells alone; ■, bone marrow cells + thymosin fraction V; ○, bone marrow cells + thymosin α-1; △, bone marrow cells + levamisole; □, bone marrow cells + theophylline.

Experimental groups receiving normal syngeneic bone marrow cells pretreated with drugs and injected iv 10 days after tumor implantation.—Tumor growth was similar in mice given injections of 3×10^7 normal bone marrow cells (group 2) whether injected on the day of tumor implantation or 10 days after implantation (tables 1, 2). Theophylline effects were not significant (groups 5 and 6). In contrast, thymosin fraction V and thymosin α-1 (groups 3 and 4) yielded significantly different results compared to those obtained from all the other groups. The difference was not so pronounced on day 17 as on day 24 after tumor implantation (table 2). By days 31 and 38 after tumor implantation, only those animals survived that had received cells pretreated with thymosin fraction V or thymosin α-1. This difference was clearly significant ($P<0.001$; text-fig. 2).

DISCUSSION

The results show that normal bone marrow cells from syngeneic animals pretreated with thymosin were able to retard tumor growth and to increase survival times of animals with MCA-induced transplantable tumors. Theophylline and levamisole showed no significant effect compared to that shown by control groups. These results confirm and expand upon data of Umiel and Trainin (*25*) who showed earlier that lymphocytes from syngeneic normal and tumor-bearing mice were able to stimulate 3LL tumor growth. In our previous studies splenocytes and thymocytes pretreated with thymosin fraction V retarded tumor growth and reduced the number of pulmonary metastases due to Lewis tumor (*10, 11*). The results parallel those obtained with other types of thymic factors in different models by Ban An Khaw and Rule (*36*) and by Cupissol et al. (*27*) and are superior to results obtained with the iv injections of thymosin alone in the same model (Cupissol, Rey, Favier et al.: In preparation).

The tumor system employed here has been characterized in the authors' laboratory (*33*) and has never demonstrated T-cell-specific cytotoxicity after mixed lymphocyte culture, antibody-dependent cell-mediated cytotoxicity or NK activities. Nevertheless, immune complexes are present during tumor growth and increase over time (*5*), and weak in vivo immunity can be obtained by tumor amputation or injection of in vitro irradiated cells, which was demonstrated with the use of the Winn assay (*33*).

We show here that tumor growth was not accelerated after iv injection of normal bone marrow cells. This was not the case for injected splenocytes and thymocytes from tumor-bearing animals or even normal lymphocytes, a T-dependent phenomenon (*9*, *10*, *26*). Thymosin not only overcame lymphocyte-induced facilitated tumor growth, but also impeded it. Bone marrow cells did not facilitate tumor growth, which may suggest that in contrast with the results presented by Duwe and Singhal (*28*), there was no suppressor cell activity expressed by bone marrow cells, at least not in our model. In contrast, bone marrow cells preincubated with thymosin retarded tumor growth as do thymocytes or splenocytes under the same conditions (*10*). This action may imply that the target cell is an immature suppressor T-cell, not yet expressing suppressor activity (*37*). In the present system, it is impossible to determine if the point of impact for thymosin involves NK cells known to be present in bone marrow. Preliminary results suggest that NK cells are not involved in this mechanism and that the thymosin effect disappears after anti-Lyt 1 antiserum treatment.

Only thymosin fraction V and thymosin α-1 were active in restarting tumor growth and increasing survival time; Levamisole and theophylline were not. We have shown that these four substances in vitro raise the number of A-RFC (*34*, *35*) in healthy and tumor-bearing patients with decreased or normal A-RFC levels (*38*). These cells correspond to a T-lymphocyte theophylline-resistant (*29*, *30*) nonsuppressor subpopulation, probably an immature T-cell subpopulation (*39*). However, we have shown that theophylline, levamisole, and thymosin can modulate induction and expression of suppressor cells induced by concanavalin A (*24*) as well as suppressor activity in patients with solid tumors (*11*). These results agree with those published by Patt et al. (*40*).

However, with the exception of thymosin fraction V and thymosin α-1, in vitro results did not correlate with in vivo animal observations for the experimental system employed or with the results of Webb et al. (*32*) for theophylline. This observation suggests that in vitro tests are not suitable for the evaluation of the immunorestorative or immunostimulatory potential of a given drug (*10*, *34*). In addition, although the thymosin fraction V and thymosin α-1 results can be paralleled, the α-1 concentration employed was 20 times less than the concentration of fraction V. It might be of interest to evaluate the effects of other subfractions, especially those of the small peptides (*23*).

The results presented take on greater significance when they are considered in the light of potential clinical application. It is striking that all the results are statistically significant when the small number of cells employed is considered. Furthermore, the results were the same with bone marrow cells injected immediately after tumor implantation and with those given 10 days later, i.e., when tumor evolution is considerably advanced. This point should be stressed since it can be compared to the human situation where diagnosis is often made after significant tumor evolution has occurred. This technique presents definite advantages since to obtain the same antitumor effect as with other methods, only a small number of bone marrow cells are necessary and much less thymosin is needed than that required for iv injection or other routes of administration (*40*, *41*). Our model can be integrated with cancer patient treatment by the introduction of autologous bone marrow cell injection after high-dose chemotherapy (*42*). We are presently evaluating this possibility.

Relationship Between Xenotransplantability and Cell Surface Properties of Ascites Sublines of a Rat Mammary Adenocarcinoma[1,2,3,4]

Susan C. Howard,[5] Steven R. Hull,[6] John W. Huggins,[5] Coralie A. Carothers Carraway,[7] *and* Kermit L. Carraway[8,9]

ABSTRACT—Cell surface properties of several ascites sublines of the 13762 rat mammary adenocarcinoma were compared in an effort to understand factors important to the xenotransplantability of these tumors into C57BL/6J mice. MAT-C, MAT-C1, and MAT-cMR6-S ascites sublines were xenotransplantable; MAT-B1, MAT-C2, and MAT-MR2-S were not. All of these sublines contained a large mucin-type sialoglycoprotein (ASGP-1) as a major cell surface component. MAT-B1 and MAT-cMR6-S ASGP-1 molecules were sulfated, but MAT-C1 and MAT-MR2-S incorporated little sulfate. The major oligosaccharide of MAT-C1 ASGP-1, a disialo-oligosaccharide, was present in very low amounts in the other sublines. ASGP-1 was detected readily in the plasma of animals with MAT-C1 or MAT-MR2-S tumors, but it was not detected readily in animals with MAT-B1 or MAT-cMR6-S tumors. Thus none of these significant features of ASGP-1 that differed among the sublines correlated with xenotransplantation. However, both MAT-C1 and MAT-cMR6-S sublines had branched cell surface microvilli. Moreover, MAT-C grown in mice after xenotransplantation had extensive, branched microvilli, even though only about 10% of the population of the cells grown in the rat had them. These results suggest that the branched microvilli may provide a protective mechanism, possibly by acting as a barrier to the approach of cytotoxic cells.—JNCI 1982; 69:33–40.

The cell surface is believed to play an important role in allowing tumors to escape immune destruction by the host (*1*). Two hypotheses have been advanced to account for the allotransplantability and xenotransplantability of the Ha subline of the TA3 mouse mammary tumor and the failure of the St subline to transplant into foreign strains and species. The first hypothesis is that the presence of a major sialoglycoprotein, called "epiglycanin," on the Ha subline masks H-2 surface antigens necessary for recognition (*2, 3*). The St subline does not contain significant amounts of epiglycanin (*4*). The second hypothesis is that shed cell surface components, including epiglycanin, interact with components of the immune system to block tumor cell destruction (*5*).

However, our recent studies on xenotransplantation of sublines of the 13762 rat mammary adenocarcinoma suggest that neither of these hypotheses can completely explain tumor cell survival in a foreign host. Both the xenotransplantable MAT-C1 and nonxenotransplantable MAT-B1 ascites sublines have a major cell surface sialoglycoprotein (ASGP-1) that represents 0.5% of the total cellular protein (*6, 7*). The rates of shedding of the glycoprotein and its fragments are similar for the two sublines (*8*). These results suggest that other factors are important in allowing the escape of the tumors from immune surveillance. Among the parameters previously shown to differ between the xenotransplantable and nonxenotransplantable sublines are cell surface morphology (*9*), cell surface receptor mobility (*9, 10*), and size and composition of sialoglycoprotein (*11*). Examination of several new sublines indicates that of these parameters morphology is most closely correlated with xenotransplantation.

MATERIALS AND METHODS

Materials.—D-[1-^{3}H]glucosamine HCl (2–6 Ci/nmol) and [^{35}S]sulfate (100 mCi/nmol) were from Amersham/Searle Corp.; Instagel was from Packard Instrument Co.; CsCl (99.99%) was a product of Varlacoid; guanidine hydrochloride (grade I) was from Sigma Chemical Co.; peanut lectin was from Miles-Yeda, Ltd.; NS-ST X-ray film was from Eastman Kodak Co.

Ascites cells were maintained as previously described (*6*). Passage and cloning of MR cells were performed as previously described (*12*).

General methods.—FITC–Con A lectin receptor redistribution (*9, 10*), D-[1-^{3}H]glucosamine and [^{35}S]sulfate incorporation in vivo (*6, 11*), ASGP-1 purification and isopyknic density gradient centrifugation in CsCl with 4 *M* guanidine hydrochloride (*6*), alkaline borohydride elimination (*6*), Biogel P-4 chromatography (*6*), and ion exchange (*11*) were

ABBREVIATIONS USED: Con A=concanavalin A; FITC=fluorescein isothiocyanate; PNA=peanut agglutinin; SDS=sodium dodecyl sulfate.

[3] A nomenclature was developed for the new sublines that would be descriptive of their origin. The "MR" designation indicates the cultured line of MAT-B cells from Mason Research Institute, Worcester, Mass. A prefix "c" is used for clones of the cultured line. The term "MAT" indicates cells grown as ascites tumors (mammary ascites tumor). The "S" is included to indicate those sublines that developed sialoglycoprotein during ascites passage [*see* (*12*)].

performed as previously described. Scanning electron microscopy was done as described previously (*9*), except that osmication was performed at 4°C for 15 minutes.

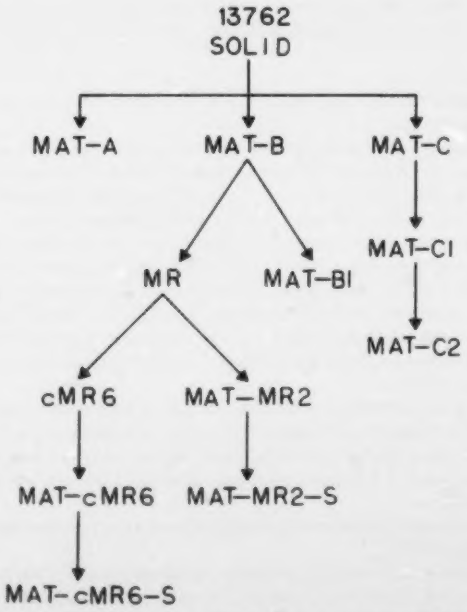
Xenotransplantation.—For each tumor line tested, C57BL/6J female mice were given injections of 1×10^6 tumor cells suspended in 0.25 ml of 0.9% NaCl (pH 7.4) (*7*). Controls received injections of 0.25 ml 0.9% NaCl.

Detection of ASGP-1 in blood plasma.—Ascites tumor-bearing rats were anesthetized with diethyl ether and decapitated by means of a guillotine. Blood was collected in a potassium oxalate-coated beaker, poured into potassium oxalate-coated Corex tubes, and centrifuged at 500×*g* for 2 minutes for cell removal. Plasma was treated with an equal volume of 5% 2-mercaptoethanol and 2% SDS in a boiling water bath for 5 minutes before electrophoresis on a 4.5-15% acrylamide gradient gel slab (*6*). The slab was stained with ^{125}I-labeled PNA and dried for autoradiography (*13*).

RESULTS

Morphology, Receptor Mobility, and Xenotransplantability of New Sublines

Text-figure 1 shows the derivation of the tumor sublines examined. Some properties of the MAT-B, MAT-B1, and MAT-C1 sublines were reported previously (*7-10*). The MAT-C1 subline exhibited highly branched microvilli and restricted Con A receptor mobility and was xenotransplantable. The MAT-B and MAT-B1 cells had a more normal surface architecture with unbranched, curved microvilli, ruffles, and ridges. Their Con A receptors were highly mobile, and the cells were not xenotransplantable. Most (90%) of the MAT-C cells had short, straight microvilli and intermediate receptor mobility and were xenotransplantable. About 10% of the population had branched microvilli (*9*).



TEXT-FIGURE 1.—Lineage of the 13762 mammary adenocarcinoma sublines.

TABLE 1.—*Xenotransplantability of 13762 ascites sublines into C57BL/6J mice*

Injection	No. of mice killed/total No. of mice[a]
Saline	0/9
MAT-B1	0/8
MAT-MR2-S	0/8
MAT-cMR6-S	6/8
MAT-C2	0/8
MAT-C1[b]	8/10
MAT-C3	0/10

[a] Numbers were identical for a 30- or 90-day period.
[b] See (7).

The new sublines were obtained from a variant (MR) of MAT-B adapted to cell culture by Dr. Erling Jensen, Mason Research Institute. MR cells were cloned (*12*), and one of the clones (cMR6) was injected into rats to give an ascites tumor line (MAT-cMR6). After about 18 passages of these ascites cells, the major sialoglycoprotein ASGP-1 appeared abruptly (*12*). These cells were called MAT-cMR6-S (*8*). Likewise, the uncloned MR cells were injected into animals to give the MAT-MR2 (an earlier passage was designated MAT-MR1) and passaged until ASGP-1 appeared at about passage 19 to give the MAT-MR2-S subline (*8*). The properties of these two variants at subsequent passages have been compared to those of MAT-B1 and MAT-C1.

The morphology of the MR cells injected into animals changed at each successive stage noted above. The MR cells (cloned or uncloned) had fewer prominent microvilli than the ascites cells derived from them (fig. 1). The most dramatic difference, however, occurred at the stage of the appearance of ASGP-1 when the MAT-cMR6-S cells exhibited branched microvilli, but the MAT-MR2-S cells did not (figs. 1C, 1F).

Treatment of the MAT-cMR6-S and MAT-MR2-S cells with fluorescent Con A did not show the dramatic differences in Con A receptor mobility previously observed between MAT-B1 and MAT-C1 cells. Neither of the new sublines underwent the extensive capping that occurred with MAT-B1 cells, although MAT-MR2-S cells did undergo a limited capping reaction. Limited receptor mobility was also observed for MAT-cMR6-S cells, but microscopic examination suggested that the effect was due to clustering of the branched microvilli rather than to the typical capping response observed with MAT-B1 cells. Thus the branched MAT-cMR6-S microvilli appear to be stabilized and to have relatively immobile Con A receptors, as previously observed for MAT-C1 microvilli. The mobility observed may be due to the apparent lower density of microvilli on MAT-cMR6-S cells than on MAT-C1 cells.

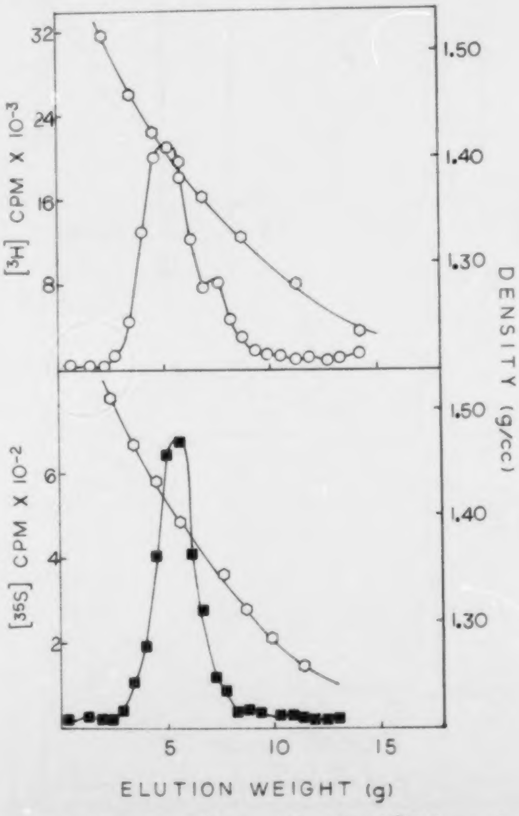
The xenotransplantability of the new sublines was tested by the injection of the sublines into C57BL/6J mice (*7*). The MAT-cMR6-S cells were approximately as efficient in killing the mice (table 1) as were the previously tested MAT-C1 cells (*7*), but none of the other sublines were active (table 1).

Sialoglycoprotein of the New Sublines

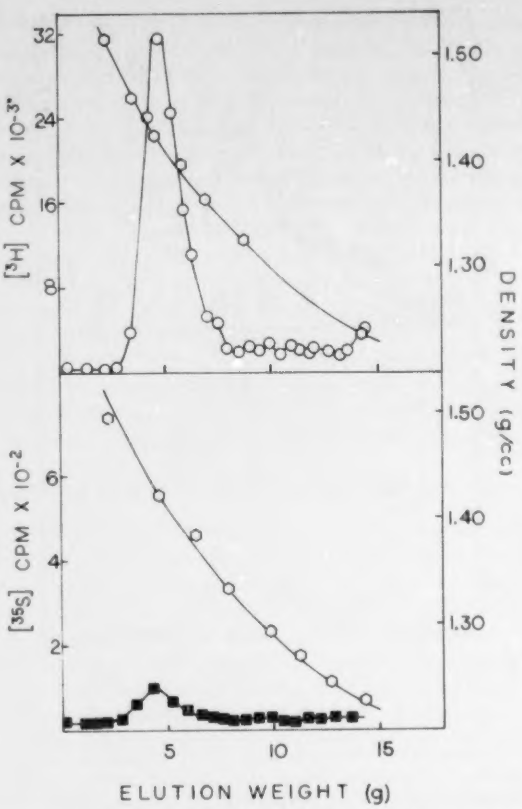
Since MAT-B1 and MAT-C1 sublines differed in oligosaccharide composition (*6*) and sulfation (*11*) of ASGP-1, the glycoprotein was isolated from each of the new sublines after double labeling with [^{3}H]glucosamine and [^{35}S]sulfate. Density gradient profiles in CsCl/4 *M* guanidine hydrochloride showed more ^{35}S label in ASGP-1 from MAT-cMR6-S (text-fig. 2) than from MAT-MR2-S (text-fig. 3).

Oligosaccharides were isolated from ASGP-1 of MAT-cMR6-S and MAT-MR2-S by alkaline borohydride treatment and fractionated on Biogel P-4. The profiles of oligosaccharides for MAT-cMR6-S (text-fig. 4) were more similar to those for MAT-B1 (*6, 11*) than to those for MAT-C1. In particular, the MAT-cMR6-S profiles showed a reduced peak II oligosaccharide characteristic of MAT-B1 ASGP-1. The oligosaccharide profile for MAT-MR2-S ASGP-1 was simpler than any observed previously.

For additional characterization, the major oligosaccharide peaks of the new sublines were further fractionated by DEAE-Sephadex chromatography, as described previously for MAT-B1 oligosaccharides (*1*). Text-figure 5 shows the column profiles of the oligosaccharides from MAT-cMR6-S on DEAE-Sephadex. The results were similar to those obtained with MAT-B1 (*11*). MAT-C1 oligosaccharides were also fractionated by sequential Biogel P-4 and DEAE-Sephadex chromatography. The DEAE-Sephadex chromatography and gas chromatography analyses of the oligosaccharide carbohydrate compositions indicated that component II-3, the acidic fraction of II from Biogel P-4, contained two sialic acid residues, two galactose, and one glucosamine per one galactosaminitol. Component II-3 had the same composition as the acidic oligosaccharide from epiglycanin of TA3-Ha mammary adenocarcinoma cells (*14*). Component III-2, the intermediate peak from DEAE-Sephadex chromatography of peak III from Biogel P-4, contained one sialic acid, one galactose, and one glucosamine per one galactosaminitol. Further structural analyses of these oligosaccharides are in progress.



TEXT-FIGURE 2.—Density gradient centrifugation of [^{3}H]glucosamine (*top*) and [^{35}S]SO$_4$$^{-2}$-labeled (*bottom*) MAT-cMR6-S membrane vesicles in CsCl gradients containing 4 *M* guanidine hydrochloride (○, ■). Density (○). MAT=ascites, MR=cultured, c=cloned, and S=sialoglycoprotein.

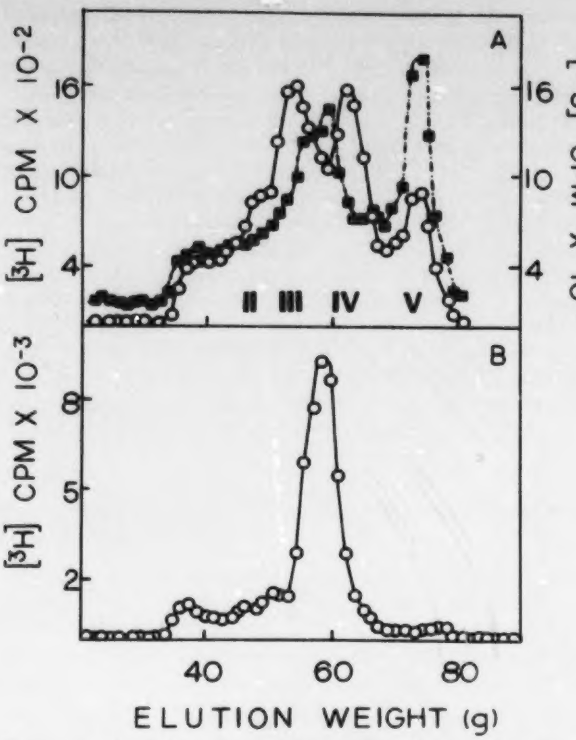


TEXT-FIGURE 3.—Density gradient centrifugation of [^{3}H]glucosamine (○) and [^{35}S]SO$_4$$^{-2}$-labeled (■) MAT-MR2-S membrane vesicles in CsCl gradients containing 4 *M* guanidine hydrochloride. Density (○).

Table 2 shows the fraction of metabolically incorporated glucosamine in these two oligosaccharides from three sublines—MAT-B1, MAT-C1, and MAT-cMR6-S. There appeared to be no obvious relationship between the content of a particular sialo-oligosaccharide and xenotransplantability. This finding was consistent with results of analyses of whole-cell sialic acid, which also did not show any correlation with xenotransplantability (data not shown).

ASGP-1 in Plasma

The rates of shedding in vitro were essentially the same for MAT-B1 and MAT-C1 sublines, but there was a 2.5-fold greater amount of soluble ASGP-1 in MAT-C1 ascitic

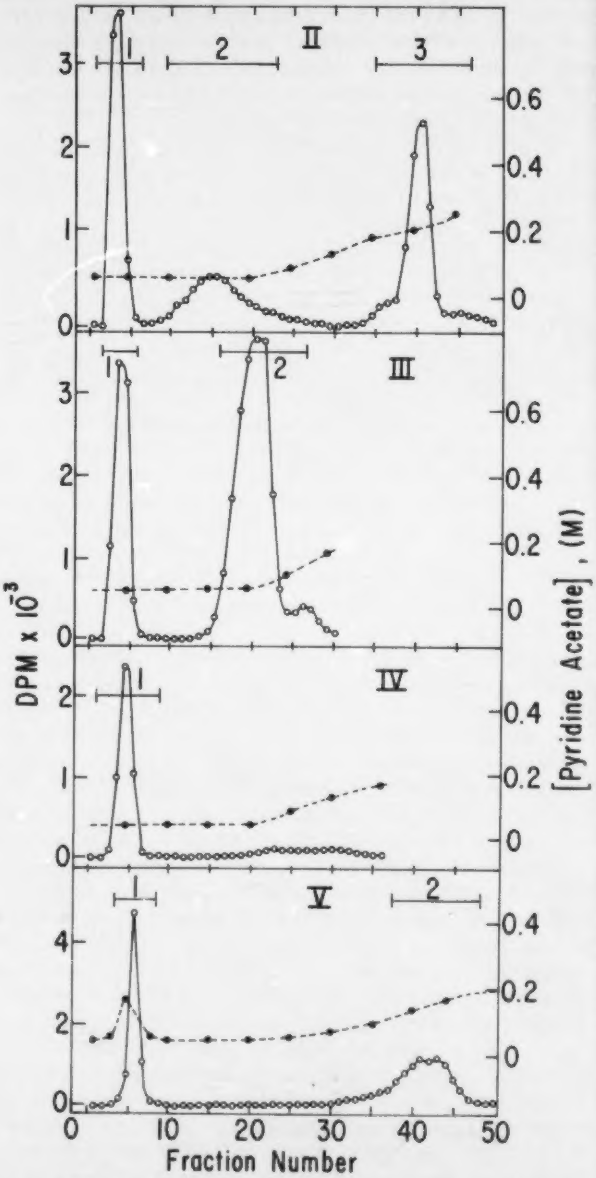


TEXT-FIGURE 4.—Gel filtration on Biogel P-4 of oligosaccharides from new sublines. A) Oligosaccharides of MAT-cMR6-S ASGP-1 labeled with $[^3H]$glucosamine (○) and $[^{35}S]$sulfate (■). B) Oligosaccharides of MAT-MR2-S (○) labeled with $[^{14}C]$glucosamine. The samples were mixed, alkaline borohydride treated (1.0 *M* $NaBH_4$, 0.05 *M* NaOH, 16 hr, 45°C), neutralized with acetic acid, and chromatographed on a Biogel P-4 column (200–400 mesh, 0.9×113 cm) equilibrated with 1.0 *M* pyridine acetate (pH 6.0). *Roman numerals* refer to the peaks with *open circles* in A.

fluid (*8*). Since antigens in blood may act as part of blocking factors to abrogate immune destruction of tumors, we assayed blood plasma for soluble ASGP-1 using radiolabeled PNA, which has been shown to bind specifically to ASGP-1 (*12*, *13*), on SDS electrophoresis gels of plasma from animals with the different ascites sublines. PNA was observed to bind to all of the sublines tested by fluorescence microscopy with the use of FITC-PNA (*15*) and to bind to the ASGP-1 molecules of all the sublines with the use of ^{125}I-labeled PNA overlays on SDS–polyacrylamide gel electrophoresis of the whole cells (*13*). Thus it can be used to estimate ASGP-1 in cells, tissues, or fluids, regardless of degree of sialylation, but it is only semiquantitative (*13*). Figure 2 shows that there were negligible amounts of plasma ASGP-1 in animals with MAT-B1 (nontransplantable) and MAT-cMR6-S (transplantable) tumors compared to those with MAT-C1 (transplantable) and MAT-MR2-S (nontransplantable) tumors. Thus there was no correlation between the amount of soluble ASGP-1 in the circulation and xenotransplantability of the tumor. The most reasonable explanation for these results is that ASGP-1 was cleared from the circulation.

Cell Surface Changes in a Variant of MAT-C1 Cells

During the course of passage of MAT-C1 cells over more than 4 years, we have noted one instance in which the tumor spontaneously changed to a new form. The morphology of the new variant, named "MAT-C2," was substantially different from that of MAT-C1. The cells did not exhibit the extensively branched microvilli of MAT-C1 cells. The predominant morphology was similar to that shown by MAT-

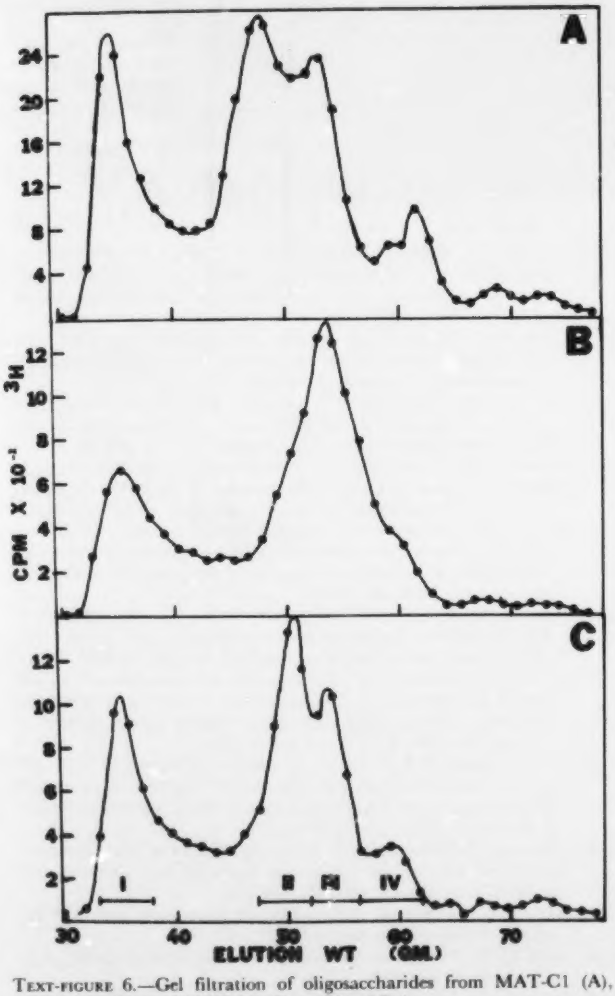


TEXT-FIGURE 5.—DEAE-Sephadex fractionation of oligosaccharides from MAT-cMR6-S. *Roman numerals* refer to fractions from text-fig. 4A. *Brackets* indicate isolated fractions used for further analyses and indicate the designations used for oligosaccharides. Thus II-3 is the oligosaccharide eluted at about fraction 40 from the column whose profile is shown in the *top graph*.

TABLE 2.—*Distribution of labeled glucosamine in oligosaccharide fractions from different sublines*

Subline	Total glucosamine, %	
	II-3	III-2
MAT-B1	12	29
MAT-C1	27	28
MAT-cMR6-S	5	22

MR2-S in figure 1. The MAT-C2 oligosaccharide pattern was simple, resembling that of MAT-MR2-S, although slightly shifted. The change in morphology and oligosaccharide was accompanied by a loss of xenotransplantability (table 1). Concomitant with these changes, a bacterial infection was discovered in the animal colony used for passage of the cells. The infectious agent was not identified specifically, although two isolates of *Staphylococcus* were obtained from the animals. The infection was eliminated by quarantine and antibiotic treatment. Passage of MAT-C2 cells was continued in the healthy animals. Over about 25 passages the ASGP-1 reverted to an oligosaccharide profile on Biogel P-4 resembling that for MAT-C1 (text-fig. 6). These cells were designated MAT-C3. They were not xenotransplantable, and few of them contained branched microvilli.



TEXT-FIGURE 6.—Gel filtration of oligosaccharides from MAT-C1 (A), MAT-C2 (B), and MAT-C3 (C) on Biogel P-4.

To determine the reason for the shift in Biogel P-4 profiles in going from MAT-C1 to MAT-C2 to MAT-C3, we fractionated the oligosaccharides by DEAE–Sephadex chromatography. The ratios of neutral oligosaccharides to monosialo- to disialo-oligosaccharides were determined for each subline from the glucosamine labeling. For MAT-C1 the ratio was 1:5:5. For MAT-C2 the ratio was 1:2:2. For MAT-C3 the ratio was 1:5:6. Thus the change in pattern appears to result primarily from a change in sialylation, MAT-C2 having a much smaller amount of sialylated oligosaccharides compared to neutral oligosaccharides than the other sublines. Whether there were other changes in these oligosaccharides (e.g., fucosylation) remains to be investigated.

Morphology of MAT-C Cells Grown in Mice

MAT-C cells were heterogeneous when grown in the rat. About 10% of the population had extensive, branched microvilli, but the remainder had short, straight microvilli (*9*). When MAT-C cells were transplanted into mice and isolated shortly before the death of the animal, most of the cells (>80%) had branched microvilli. These results suggested a selection mechanism favoring the cells with branched microvilli and provided support for the concept that morphology is important for survival of tumor cells in the foreign species.

DISCUSSION

In previous studies a number of differences have been noted between MAT-B1 and MAT-C1 ascites sublines of the 13762 rat mammary adenocarcinoma that might be related to their differences in xenotransplantability. Several new sublines, obtained by ascites passage of a cultured subline of the tumor (*12*), have been examined in an attempt to understand the reason for the xenotransplantability difference.

One difference of particular interest between the sublines was the sialic acid content of the major sialoglycoprotein ASGP-1. MAT-C1 ASGP-1 had a threefold higher content of sialic acid than MAT-B1 ASGP-1. The difference was primarily due to a larger amount of disialohexasaccharide on the MAT-C1 ASGP-1. However, the amount of disialohexasaccharide did not correlate with xenotransplantability (table 2), since the new subline MAT-cMR6-S, which was xenotransplantable, had a low content of disialohexasaccharide. Moreover, in the change from MAT-C1 to MAT-C2 to MAT-C3 cells, there was a loss and then a reappearance of the disialohexasaccharide with a loss but not a reappearance of xenotransplantability.

These changes in oligosaccharide during and after an infection of the animals suggest that a selection process was occurring in response to the changing immunologic status of the animal. The simplest explanation is that cells with highly sialated ASGP-1 were favored in the healthy animals, whereas cells with more poorly sialated ASGP-1 were favored in the infected animals.

Plasma ASGP-1	–	+	–	+++	+

[a] Symbols indicate relative amounts of plasma ASGP-1 cells showing redistribution. –=0; +=0.25; +++=1. ND=not determined.

The absence of sulfate (*11*) is also not required for xenotransplantation, as indicated by results with the MAT-cMR6-S subline (table 3). Likewise, extensive receptor redistribution (*8*, *10*) is not necessary for prevention of xenotransplantation, and the blood plasma concentration of soluble ASGP-1 appears unrelated. The only parameter for the sublines studied that correlated with xenotransplantability was cell morphology. However, the results should not be construed to indicate that morphology is the only important factor. Other parameters not evaluated in this work may also be important. Moreover, xenotransplantation may depend on a combination of cell surface parameters including those above, none of which is absolutely essential.

If morphology can play a role in aiding tumor cells to escape immunologic defense mechanisms, it is instructive to consider possible contributions of the branched microvilli to tumor cell survival. If the mechanisms for killing tumor cells involve cell-to-cell contact, the branched microvilli provide a formidable physical barrier to a close encounter. Whereas unbranched microvilli may interdigitate and facilitate cell-to-cell interactions, no interdigitation appears feasible with the branched structures on these cells. The structure and stability of the branched microvilli (*10*, *16*) mitigate against deformation, which may be an important consideration to immune destruction (*17*). Moreover, the increased surface area permitted by the branched microvilli could increase the amount of sialoglycoprotein available at the cell periphery because of the increased depth of the sialoglycoprotein layer, effectively enhancing the cell surface charge density. Mobility of antigens on microvilli of some cells appears to be restricted (*18*). In MAT-C1 cells mobility of cell surface antigens (*9*), as well as Con A-binding molecules (*9*, *10*), is restricted. If antigen mobility is a prerequisite for immune killing (*19*, *20*), this restriction might aid in tumor cell survival. Clearly, there are a number of ways in which morphology can contribute to tumor cell survival. The significance of these possibilities is being evaluated by further experimentation.

The correlation of morphology and xenotransplantation should not suggest that the presence of ASGP-1 or the glycoprotein shedding is unimportant to tumor cell survival. These factors may contribute to survival of the tumors in syngeneic or allogeneic hosts. The cells probably develop a battery of survival mechanisms against host defenses which can be used individually or collectively against different levels of host defense mechanisms.

Steroid Hormone Receptors in the Rat Mammary Adenocarcinoma Induced by *N*-Hydroxy-*N*-2-fluorenylacetamide[1,2,3,4]

Sara Antonia Li,[5,6] Danuta Malejka-Giganti,[7] *and* Jonathan J. Li[5,8]

ABSTRACT—The steroid hormone receptors in *N*-2-fluorenylacetamide (2-FAA)- and *N*-hydroxy-2-FAA-induced mammary adenocarcinomas in outbred Sprague-Dawley rats were analyzed. Both 8S and 4S estrogen-binding components have been detected in cytosols of these tumors following sucrose gradient sedimentation in low salt. Competitive binding analyses of this binder indicated a specificity profile expected of an estrogen receptor. Both androgen and progesterone receptors were also present in the cytosols of these mammary tumors. While the androgen receptor sedimented in the 8S region of the gradient, the progestin binder appeared only as a 4S moiety under similar conditions. The relative concentrations of these receptors (expressed in fmol/mg protein ± SE) were: 17β-estradiol (28.6±4.1) > 5α-dihydrotestosterone (8.5±2.2) > progesterone (5.0±1.3). The progesterone receptor was increased at least eightfold in the mammary adenocarcinomas from ovariectomized rats that were treated with diethylstilbestrol for 6 days. Binding equilibrium data indicated $K_a=1.2–1.8\times10^9\ M^{-1}$ for the above cytoplasmic hormone receptor complexes (K_a, association constant). Although cytosols prepared from lactating mammary gland contained appreciable quantities of glucocorticoid receptor, only trace amounts were found in the mammary adenocarcinoma.—JNCI 1982; 69:41–45.

2-FAA and *N*-hydroxy-2-FAA administered systemically are mammary gland carcinogens in female Sprague-Dawley rats (*1, 2*). A single dose of *N*-hydroxy-2-FAA administered topically or ip also yields a high tumor incidence in the mammary gland of these rats (*3, 4*).

The presence of steroid hormone receptors in certain endocrine tumors has been used as an indicator of the hormone responsiveness of these tumors (*5–8*). Analyses of steroid hormone receptors in human breast cancers and in experimental mammary tumors show a multiplicity and varying amounts of these receptors (*8–16*). The DMBA-induced mammary adenocarcinoma in the rat is the most extensively studied experimental model; receptors for estrogen, progesterone, androgen, glucocorticoid, and prolactin have been characterized (*10–15*). However, the composition of steroid hormone receptors in 2-FAA- or *N*-hydroxy-2-FAA-induced mammary adenocarcinoma has not been studied. The present investigation was undertaken to characterize the steroid hormone receptors in 2-FAA- and *N*-hydroxy-2-FAA-induced mammary carcinomas in outbred Sprague-Dawley rats and to compare the levels of hormone receptors found in these mammary tumors with those found in lactating mammary glands of rats of the same strain.

MATERIALS AND METHODS

Animals, compounds, and treatment.—Four-week-old female outbred Sprague-Dawley rats (Holtzman Co., Madison, Wis.), housed individually, were fed a semisynthetic diet containing 20% casein (*17*). 2-FAA (mp 196°C and *N*-hydroxy-2-FAA (mp 150–151°C) were prepared as previously described (*1, 3*) and shown to be authentic by UV and infrared spectra as well as by thin-layer chromatography. The compounds were dispersed in 7% gum arabic in 0.15 *M* NaCl at a concentration of 10 mg/ml. The suspended compounds were injected ip three times weekly for 4 weeks at a dose level of 0.01 mmol/100 g body weight (*2*). After the treatment was completed, the animals were weighed and examined for tumors once weekly. The earliest mammary tumors were palpable at about 3.3 or 1.9 months after treatment with 2-FAA or *N*-hydroxy-2-FAA, respectively, had ceased. Rats bearing mammary tumors of sufficient sizes (1–2 cm^3) were ovariectomized 48 hours before use. Since a preliminary study indicated similar characteristics and levels of steroid receptors in both 2-FAA- and *N*-hydroxy-2-FAA-induced mammary adenocarcinomas, all data presented herein were obtained from mammary tumors induced by *N*-hydroxy-2-FAA. Groups of ovariectomized rats bearing mammary tumors were treated for 6 days with a single DES pellet (20 mg) implanted sc in each rat as previously described (*18*). The pellet was removed 48 hours before the excision of tumors. Samples of all mammary

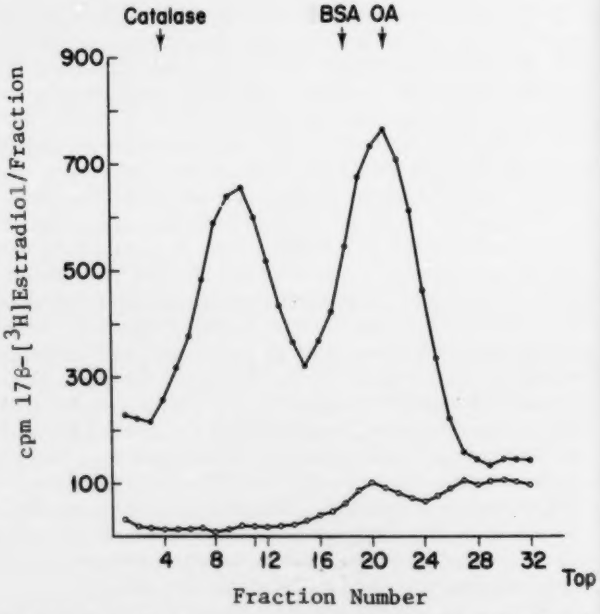
tumors were fixed in buffered Formalin and then sectioned. The 5- to 6-μm-thick sections were stained routinely with hematoxylin and eosin for histologic examination. Of the carcinogen-induced mammary tumors, 65% were adenocarcinomas. The mammary fibroadenomas and adenomas were not included in the steroid receptor analyses presented herein. Lactating rats were decapitated on days 13–14 of lactation. The mammary tissues of lactating rats and mammary adenocarcinomas were excised and placed in cold 0.15 *M* NaCl in TEDT buffer (pH 7.4).

Receptor analyses.—Tumor samples were separated from necrotic or hemorrhagic regions, and all tissues studied were trimmed of fat and connective tissue. The normal and tumor tissues were minced, rinsed, and then homogenized on ice in 2 volumes of either TEDT buffer or TEDT buffer containing 10% glycerol, depending on the hormone binder to be examined (*19*). A Polytron-type PT-10 homogenizer (Kinematica GMBH, Lucerne, Switzerland) was used for the disruption of the mammary glands and tumors at four 3-second bursts and at a rheostat setting of 3 0. Homogenates were then centrifuged at 100,000×*g* for 1 hr at 4°C in a Spinco L2-65B ultracentrifuge. Supernatant fractions were passed through Millipore filters (Millex, 0.45 μm; Millipore Corp., Bedford, Mass.) to remove lipid and particulate matter (*18, 19*). Aliquots of the filtered cytosols containing approximately 17 mg protein/ml were incubated with the appropriate radioactive steroid at 2.5–10 n*M* 17β-[2,4,6,7-^{3}H]estradiol (105 Ci/mmol), [1,2,6,7-^{3}H]progesterone (103 Ci/mmol), [17α-*methyl*-^{3}H]R 5020 (86 Ci/mmol), 5α-[1,2,6,7-^{3}H]DHT (80 Ci/mmol), or [6,7-^{3}H]dexamethasone (38 Ci/mmol) (New England Nuclear Corp., Boston, Mass.) alone or in combination with the corresponding radioinert hormone at one hundredfold-excess concentrations. Antiestrogens when used in competitive binding assays were incubated at five hundredfold-excess concentrations. Following the 90-minute incubation period, cytosols were assessed for radioactivity and then treated with DC to separate unbound steroids as described previously (*18, 19*). DC treatment was for 12 minutes for progestin binding and 1 hour for estrogen, androgen, and glucocorticoid binding. Preliminary experiments indicated that these time periods were sufficient for optimal removal of unbound hormone and some of the hormone from lower affinity binding components. The labeled cytosols were layered on 4.6-ml linear 5–20% sucrose gradients prepared in TEDT buffer with the use of a Buchler gradient former. The samples were centrifuged for 17 hours at 39,000 rpm in a Spinco SW50.1 rotor at 4°C. Gradient tubes were pierced and nine-drop fractions were collected in scintillation vials. Radioactivity sampling and measurements have been reported earlier (*20*). Catalase (11.3S), bovine serum albumin (4.6S), ovalbumin (3.7S), γ-globulin (7.0S), and myoglobin (2.0S) served as sedimentation standards. We calculated sedimentation coefficients of the radioactive peaks by using the method of Martin and Ames (*21*). We determined protein concentration of the cytosols by the method of Lowry et al. (*22*), using bovine serum albumin as a standard.

Scatchard analyses (*23*) of binding affinities for estrogen, androgen, and progestin binders were performed at cytosol protein concentrations of 4–6 mg/ml. Aliquots of these appropriately diluted cytosols were incubated with varying concentrations (1–12 n*M*) of labeled hormones for 22 hours on ice with constant agitation to attain equilibrium according to the method of Ellis and Ringhold (*24*). We subtracted nonspecific binding from these data, using corresponding nonlabeled hormones at one hundredfold excess at each concentration. These data were corrected for background (cytosol without added radioactivity). Scatchard plots were subjected to linear regression analysis with the use of an HP-97 Hewlett programmable calculator.

RESULTS

Estrogen binding in mammary adenocarcinoma and in lactating mammary gland.—Estrogen binding in cytosols of either 2-FAA- or *N*-hydroxy-2-FAA-induced mammary carcinomas exhibited a discrete 8S binding component and a smaller 4S binding moiety (text-fig. 1). The size of the 4S component varied and was absent in some of the mammary tumor cytosol preparations. The 8S peak was completely abolished by either one hundredfold-excess nonlabeled 17β-estradiol or DES, whereas the 4S peak was only partially inhibited. The lactating mammary gland also contained a similar cytosolic 8S plus 4S estrogen binder. The specificity of the estrogen receptor in both these tissues was demonstrated by the inability of corticosteroids as well as androgen and progesterone to compete with the radiolabeled 17β-estradiol for binding (table 1). Both nafoxidine hydrochloride (U-11100A)—1-[2-[*p*-(3,4-dihydro-6-methoxy-2-phenyl-1-



Text-figure 1.—Representative sucrose gradient profiles of *N*-hydroxy-2-FAA-induced mammary adenocarcinoma cytosol fraction from ovariectomized rats after in vitro incubation with 2.5 n*M* tritiated 17β-estradiol in the presence (○) or absence (●) of one hundredfold-excess radioinert 17β-estradiol. The cytosols were then treated with DC for 1 hr. Each 5–20% sucrose gradient contained 0.3 ml cytosol. Protein concentration of the cytosol was 18.5 mg/ml. Catalase, bovine serum albumin (BSA), and ovalbumin (OA) are indicated as sedimentation markers.

TABLE 1.—*Effect of various steroids on the binding of labeled 17β-estradiol to the cytosols of* N-*hydroxy-2-FAA-induced mammary adenocarcinoma and mammary gland of lactating rats*

Nonlabeled steroid[a]	Percent inhibition[b]	
	Adenocarcinoma	Mammary gland
17β-Estradiol	86	83
DES	79	75
Ethinylestradiol	83	73
Progesterone	0	3
5α-DHT	0	9
Hydrocortisone	0	5
Aldosterone	0	2
Enclomiphene citrate[c]	57	48
Nafoxidine HCl	73	54
MER-25	26	38

[a] Aliquots of mammary adenocarcinoma or mammary gland cytosol (16 mg protein/ml) were incubated at 0–3°C in a total vol of 0.5 ml with 2.5 nM tritiated 17β-estradiol alone or in combination with competing nonradioactive steroids (2.5×10^{-7} M) for 90 min. Free hormone was removed by DC absorption (1 hr).

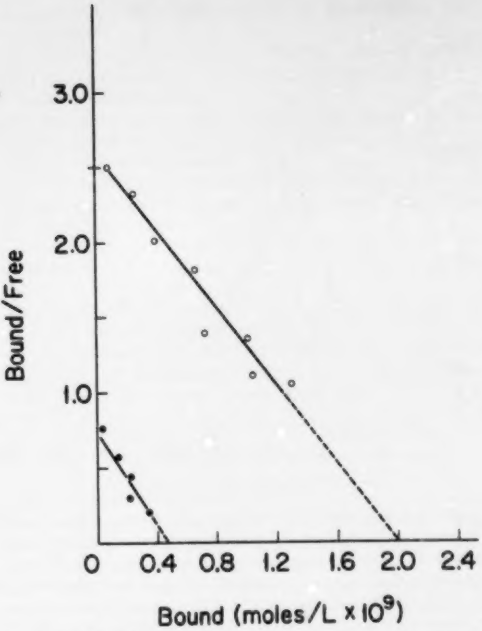
[b] Radiolabeled 17β-estradiol concentration in these cytosols, without competitor, corresponded to 0% inhibition. Values are based on the mean of triplicate determinations in separate experiments.

[c] Radioinert antiestrogens were used at 12.5×10^{-7} M.

naphthyl)phenoxy]ethyl]pyrrolidine hydrochloride—and enclomiphene citrate—1-[*p*-(β-diethylaminoethoxy)phenyl]-1,2-diphenyl-2-chlorethylene monocitrate—were effective competitors at five hundredfold-excess concentrations. However, MER-25 exhibited notably less reduction of the labeled 17β-estradiol at this concentration.

Scatchard analyses and estrogen receptor concentration.—Cytosol fractions of mammary adenocarcinoma induced by *N*-hydroxy-2-FAA were incubated with varying concentrations (1–12 nM) of radioactive 17β-estradiol at 0–3°C. A Scatchard plot of the data showed a single class of high-affinity, low-capacity binding sites with a K_a of 1.3×10^9 M^{-1} similar to that found for lactating mammary gland (2.0×10^9 M^{-1}) (text-fig. 2). The amount of cytoplasmic estrogen receptor found in *N*-hydroxy-2-FAA-induced mammary adenocarcinoma (table 2) was almost twice the level found in 13- to 14-day lactating mammary glands.

Progestin receptor and induction by estrogen.—The concentration of specific progestin binding was low in the mammary adenocarcinoma of ovariectomized rats (table 2). When a 20-mg DES pellet was implanted for 6 days in ovariectomized rats bearing mammary adenocarcinomas, we found an eightfold increase in specific progestin binder (table 2), using [^{3}H]R 5020 as ligand. Competition for the progesterone receptor was essentially complete (>90%) in the presence of either one hundredfold-excess radioinert progesterone or R 5020. Binding specificity was assessed by the low level (<7%) of competition by either 17β-estradiol, hydrocortisone, or triamcinolone acetonide—9-fluoro-11β,21-dihydroxy-16α,17-[1-methylethylidenebis(oxy)]pregna-1,4-diene-3,20-dione. However, 5α-DHT partially inhibited (49%) the labeled R 5020 or progesterone binding at the same concentration. Under conditions of the receptor assay, serum derived from either untreated or DES-treated rats exhibited little specific progestin binding with the use of tritiated R 5020. Therefore, it was unlikely that the 4S progesterone



TEXT-FIGURE 2.—Scatchard analyses of specific cytoplasmic estrogen receptor in *N*-hydroxy-2-FAA-induced mammary adenocarcinoma (○) and lactating mammary gland (●). Incubations were done at 1–10 nM for 22 hr at 3°C to attain equilibrium and then treated with DC (1 hr). Nonspecific binding was subtracted from these data with the use of nonlabeled 17β-estradiol at one hundredfold-excess concentration at each data point. Protein concentration was 9.0 mg/ml for *N*-hydroxy-2-FAA-induced mammary tumor and 9.5 mg/ml for lactating mammary gland. L=liter.

[a] ND=not detectable.

[b] Sedimented in low-salt medium. Sedimentation values were determined according to the method of Martin and Ames (*21*) with the use of five standards.

[c] Calculated from Scatchard plots. Protein concentration ranged from 4 to 6 mg/ml. Data represent the means of three separate determinations at 0–3°C.

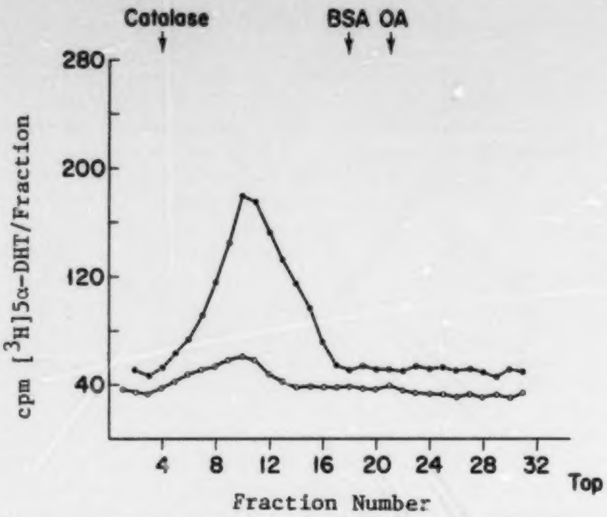
[d] Values are means ± SEM. No. of individual determinations indicated *in parentheses.*

[e] Determinations were performed on cytosols derived from 13- to 14-day lactating rats.

[f] $P<0.01$, compared with value for the tumor.

[g] $P<0.05$, compared with value for the tumor.

[h] Ovariectomized rats were treated for 6 days with a 20-mg DES pellet implanted sc. Pellets were removed 48 hr before excision of tumors.



TEXT-FIGURE 3.—Representative sucrose gradient patterns of cytosolic androgen receptor in *N*-hydroxy-2-FAA-induced mammary adenocarcinoma from 48-hr ovariectomized rats. Incubations were done at 2.5 n*M* [^{3}H]5α-DHT alone (●) or in combination with one hundredfold-excess radioinert 5α-DHT (○). Following DC treatment (1 hr), aliquots of 0.3 ml were applied to each gradient. Protein concentration was 17.8 mg/ml. Catalase, bovine serum albumin (BSA), and ovalbumin (OA) served as sedimentation coefficient standards, as previously indicated.

receptor observed in mammary tumor cytosols of estrogen-treated rats was due to appreciable binding of this radiolabeled ligand to serum proteins. Scatchard analyses of the progesterone receptor (table 2) indicated that the affinity constant for this binder was in the same range as that for the estrogen receptor in the mammary tumor. The amount of progesterone receptor in lactating mammary glands significantly exceeded the level in *N*-hydroxy-2-FAA-induced mammary tumors.

Androgen binding in mammary adenocarcinoma.—Specific androgen binding was determined in cytosols of *N*-hydroxy-2-FAA-induced mammary adenocarcinomas. Following sucrose gradient centrifugation, a single 8S component was observed with the use of labeled 5α-DHT (text-fig. 3). Competition performed at one hundredfold-excess unlabeled 5α-DHT was appreciable (72%). In contrast, adrenocorticoids and DES did not exhibit significant competition for the 8S androgen receptor, whereas 17β-estradiol partially inhibited (51%) the binding of radioactive androgen to the receptor at one hundredfold-excess concentration. The amount of specific androgen binding in cytosols of lactating mammary glands, however, was undetectable.

Comparison of glucocorticoid binding in the lactating mammary gland and mammary tumor.—Although mammary gland cytosols of the 13-day lactating rats contained appreciable quantities of 8S glucocorticoid receptor (table 2) confirming a previous report (*13*), cytosols of mammary adenocarcinomas induced with *N*-hydroxy-2-FAA contained no detectable amounts of glucocorticoid binding.

DISCUSSION

The presence of estrogen, progesterone, androgen, and glucocorticoid receptors in human breast cancer cells is well documented (*5, 8, 9, 11*), and the use of multiple receptor assays in the evaluation of these tumors to predict response to hormone therapy is gaining appreciation. Of the carcinogen-induced rat mammary adenocarcinomas examined for steroid receptors, variable quantities of estrogen, progesterone, and glucocorticoid receptors have been described (*10, 11, 13, 14*). Recently, androgen receptors have also been shown in DMBA- and MNU-induced rat mammary tumors (*15, 16*). The level of steroid receptors in normal mammary gland as well as in chemically induced mammary carcinomas is highly dependent on the endocrine state of the animal. Under comparable conditions, the concentration of estrogen receptor in lactating mammary glands of ovariectomized rats found in the present study is similar to values previously reported (*8, 25–27*). Moreover, the amounts of both progesterone and glucocorticoid receptors in these mammary tissue cytosols are within the same range described elsewhere (*8, 28*). Between *N*-hydroxy-2-FAA-induced mammary tumors and other chemically induced mammary adenocarcinomas there are both similarities and differences in steroid receptor concentrations. The level of cytosolic estrogen receptor in *N*-hydroxy-2-FAA-induced mammary tumors is comparable to the levels of 8S plus 4S receptors found in either DMBA- or MNU-induced mammary carcinomas (*16, 29–31*) but nearly twelvefold higher than the level found in R3230AC transplantable rat mammary tumors (*30*). Since the quantity of progesterone receptor in various carcinogen-induced mammary carcinomas has been shown to be highly sensitive to either ovariectomy or hypophysectomy (*16, 29, 32*), the low level of progestin binder in *N*-hydroxy-2-FAA-induced mammary adenocarcinomas determined in this study may be expected. A nearly eightfold increase in specific R 5020 binding was obtained in *N*-hydroxy-2-FAA-induced mammary tumors in estrogen-primed animals. Increases in progesterone receptor have been demonstrated previously in DMBA-induced mammary carcinomas after estrogen treatment (*32, 33*). However, the level of androgen binder in *N*-hydroxy-2-FAA-induced mammary adenocarcinomas is markedly higher than the nil levels found in lactating mammary glands and twice the level seen in MNU-induced mammary tumors (*16*) but considerably lower than the level of 7S binder in DMBA-induced mammary carcinomas (*15*). The most striking difference between *N*-hydroxy-2-FAA-induced mammary tumors and other chemically induced tumors of the mammary gland is the absence of significant amounts of glucocorticoid receptor compared to the presence of high levels of 7–8S binder in both DMBA-induced mammary tumors and R3230AC transplantable mammary neoplasms (*8, 13*), as well as in lactating mammary glands. As a result of these findings, the *N*-hydroxy-2-FAA-induced mammary adenocarcinoma appears to be useful in delineating receptor interactions of certain hormonal agents, such as synthetic progestins in which glucocorticoid binding would interfere.

Platinum-Complexed Antitumor Immunoglobulins That Specifically Inhibit DNA Synthesis of Mouse Tumor Cells[1,2,3]

Esther Hurwitz,[4] **Rina Kashi,**[4] *and* **Meir Wilchek**[4,5]

ABSTRACT—Platinum salts were complexed with antitumor reactive immunoglobulins (Ig). The Pt-complexed antitumor Ig retained their specific antibody binding activity. The inhibition of DNA synthesis by Pt salts (K_2PtCl_4 and *cis*-diamminedichloroplatinum II) and Pt-Ig complexes was studied in 2 tumor cell lines of mice. The Pt-Ig complexes were much more effective inhibitors of DNA synthesis when complexed with Ig, which had binding affinity toward the test tumor cells.—JNCI 1982; 69:47–51.

Platinum-containing complexes in general and *cis*-DDP in particular are effective antitumor agents (*1*, *2*). The therapeutic effectivity of such complexes was demonstrated in various experimental animal models (*3*–*5*). Furthermore, *cis*-DDP is now widely used clinically and is considered to be an effective drug against metastatic testicular and ovarian carcinoma.

The major drawback of *cis*-DDP, as with many other anticancer agents, is its high degree of toxicity (*6*, *7*). Other Pt complexes such as condensation products with various amides, mainly the nucleic acid bases uracil and thymine (Pt blues) or Pt complexes with diaminocyclohexanes have been developed. Many such cis-diaminoplatinum derivatives exhibited antitumor activity in vivo and were less toxic (*8*, *9*).

Antitumor antibodies have been used by us and others as carriers of a number of chemotherapeutic agents in an attempt to increase the chemotherapeutic agents' specificity toward the tumor cells and thereby reduce the agents' general toxicity (*10*–*12*). When applied in vivo in some tumor systems (*12*) mixtures of antitumor antibodies and drugs were more effective than either of them separately.

We have tested the use of antitumor Ig as Pt carriers to tumor cell-reactive Ig and used them as inhibitors of DNA synthesis in vitro. Similar complexes have been prepared by others (*13*), but they were used only in crystallographic studies.

Pt–Ig complexes with specificity toward a particular tumor cell were found to be more efficient in inhibiting DNA synthesis by that cell than was Pt complexed to normal Ig or to serum albumin. In 1 tumor cell line in which the Pt salts K_2PtCl_4 and *cis*-DDP inhibited DNA synthesis, only at high concentrations, Pt–antitumor Ig was a much more effective inhibitor.

MATERIALS AND METHODS

Tumor cells.—Two types of tumor cells were used: *a*) Moloney virus-induced lymphoma or YAC cells (*14*) maintained in vivo in inbred A/J male mice and *b*) a B-cell leukemia, 38C13, produced in inbred C3HeB mice by induction with 7,12-dimethylbenz[*a*]anthracene (*15*). For the experiments the tumor cells were kept in culture in RPMI-1640 medium containing 10% FCS and glutamine antibiotics, and, in the case of 38C13 cells (*16*), 5×10^{-5} *M* β-mercaptoethanol.

Ig.—Anti-YAC was produced in goats by injection of a soluble papain digest of the YAC cell membrane as described previously (11). These antibodies were preferentially more cytotoxic to YAC cells, but they were not specific in their binding capacity. The anti-38C13 was produced by Dr. J. Haimovich when goats received injections of a 38C13 cell surface IgM. In each case the Ig fraction was precipitated from the antisera by ammonium sulfate at 33% saturation. A mouse-specific anti-YAC IgM was produced from a hybridoma line according to (*17*). The IgM was precipitated from mouse ascitic fluid by ammonium sulfate at 45% saturation.

The Ig–Pt complex preparation.—The Pt–Ig complex was prepared by the reaction of 10 mg Ig at a concentration of 50 mg/ml PBS [0.15 *M* NaCl–0.01 *M* phosphate (pH 7.2)] with 0.3 mg K_2PtCl_4 (Ventron Corp., Danvers, Mass.) at a concentration of 6 mg/ml in 0.1 *M* phosphate buffer (pH 6.4) for 2–3 hours at room temperature. The resulting material was applied to a Biogel P-60 column (Bio-Rad Laboratories, Richmond, Calif.) run in 0.1 *M* phosphate buffer at pH 6.4 for the separation of bound from free Pt (text-fig. 1). The amount of complexed Pt was assayed *a*) by a combination of ion exchange, resin-loaded papers, and X-rays spectrography (performed by Mr. L. E. Weeks, Monsanto Co., St. Louis, Mo.) (*18*) and *b*) by the unbound Pt determined spectrophotometrically (*19*); the complexed Pt was obtained from the difference between the total and the unbound Pt. Free Pt was separated from bound Pt by ultrafiltration through conical membranes (Centriflo; Amicon, Oosterhout, Holland).

Evaluation of antitumor activity.—Inhibition of DNA synthe-

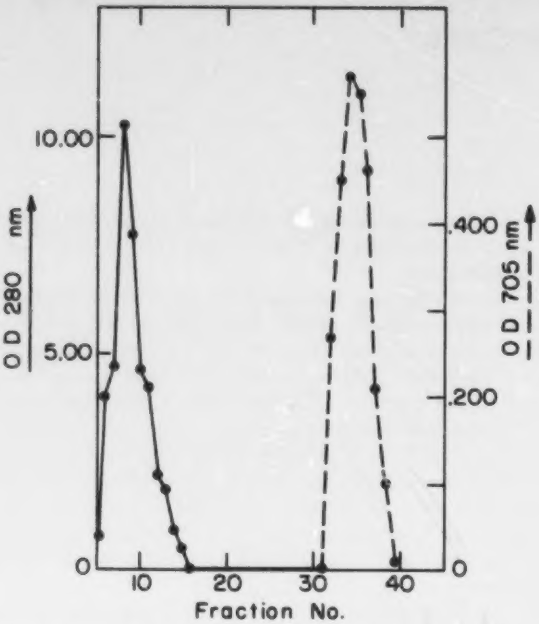
[5] We thank Dr. J. Haimovich, Tel-Aviv University, Tel-Aviv, Israel, for the 38C13 cell line, for the goat antiserum to the surface IgM, and for the [^{3}H]IgM 38. We appreciate the Physical Sciences Center, Monsanto Co., St. Louis, Mo., for assaying the platinum content of some of the platinum-immunoglobulin complexes.



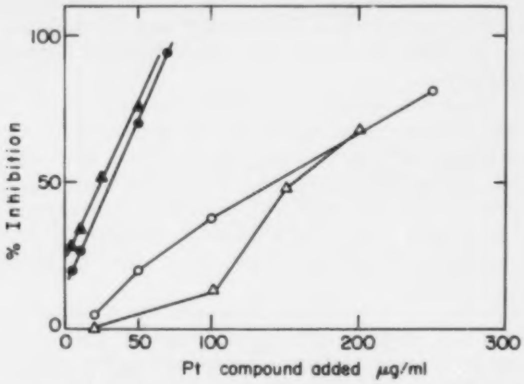
TEXT-FIGURE 1.—Fractionation of Pt-goat anti-YAC Ig for the separation from unbound Pt. After Pt was complexed with Ig, the material was applied to a column of Biogel P-60 (16×2 cm; Bio-Rad Laboratories) developed in 0.1 *M* phosphate buffer at pH 6.4. Fractions of 1 ml were collected. The Ig-Pt was determined by absorbance at 280 nm (——). Aliquots of the unbound Pt were analyzed spectrophotometrically by absorbance at 705 nm (- - -). OD=optical density.

sis by K_2PtCl_4, *cis*-diamminedichloroplatinum II (Bristol, Syracuse, N.Y.), and the Ig-Pt complexes was determined by a method similar to the one in (*10*). The tumor cells ranging from 1×10^4 to 5×10^5/ml were suspended in their suitable growth media (RPMI-1640 containing 10% FCS. The cells were dispensed in 100-μl aliquots into the wells of Microtiter plates (MicroTest II 3040; Falcon Plastics, Oxnard, Calif.). The Pt compounds were added to the cells in 50-μl amounts. The plates were incubated for 2-3 hours at 37°C in a humidified atmosphere of 5% CO_2 in air. At that time, 10 μl of 0.3 μCi [*methyl*-^{3}H]dThd (6.25 Ci/mmol; Nuclear Research, Be'ér-Sheva, Israel) was added to each well, and the plate was incubated for 20 hours as above. The [*methyl*-^{3}H]dThd incorporation was close to linear at this period of incubation. The reaction was terminated by TCA precipitation as described in (*10*).

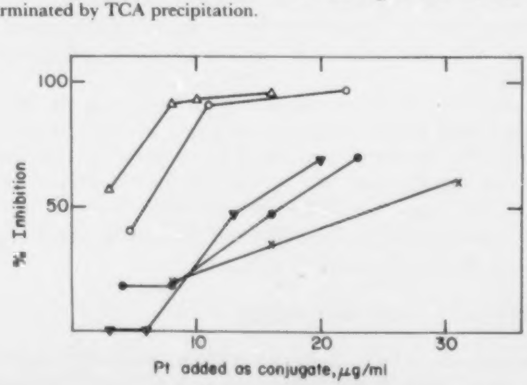
The antibody activity.—The antibody activity of the Ig-Pt complexes was determined by one of the three following methods: *a*) complement-mediated lysis—tumor cells, 5×10^5/ml, in 50 μl RPMI-1640 plus 10% FCS were mixed with the 50 μl of antibody solutions, incubated for 40 minutes at room temperature, centrifuged, and washed. Fresh guinea pig serum, diluted 1:5, was added to cells (100 μl/tube). After 1 hour of incubation at 37°C, the number of dead or damaged cells was counted by trypan blue staining. *b*) Indirect binding assay—antibody solutions diluted in PBS (50 μl) were added to 5×10^5 YAC cells in 100 μl RPMI-1640 for 1 hour at room temperature. After two washings, ^{125}I-labeled goat anti-mouse (Fab')$_2$ (*16*) (^{125}I-labeled goat anti-mouse antibodies were separated from unbound ^{125}I by gel filtration on Sephadex G-25) was added and allowed to stand for another hour at room temperature. After an additional two washings of the cells, the contents in the wells were cut and enumerated in a gamma counter. *c*) Direct binding to radiolabeled antibody—the surface IgM of leukemia 38C13 was labeled by [^{3}H]leucine. Dilutions of the antibodies were made in normal goat serum, and 50-μl aliquots were mixed with 50 μl of ^{3}H-labeled IgM 38 (40,000 cpm) (*20*). After 30 minutes at room temperature, rabbit anti-goat serum was added and kept overnight at 4°C. After centrifugation the precipitate was dissolved in 1 *M* NaOH, transferred into scintillation fluid, and counted.

RESULTS

Complexes of Pt were prepared with several Ig, such as NGIg, goat anti-YAC Ig, goat anti-38C13 Ig, mouse anti-YAC monoclonal IgM, and HSA. The concentration of the reactants and the incubation time were varied in the differ-



TEXT-FIGURE 2.—Inhibition of DNA synthesis by Pt salts. The inhibition of DNA synthesis by the platinates (*cis*-Pt and K_2PtCl_4) was measured by the platinates' effects on the incorporation of [*methyl*-^{3}H]dThd. YAC cells (10^5/well) (●, ▲) or leukemia 38C13 cells (2×10^4/well) (○, △) were incubated with Pt salts for 2-3 hr at 37°C, after which [*methyl*-^{3}H]dThd was added; incubations were continued overnight. The reaction was terminated by TCA precipitation.

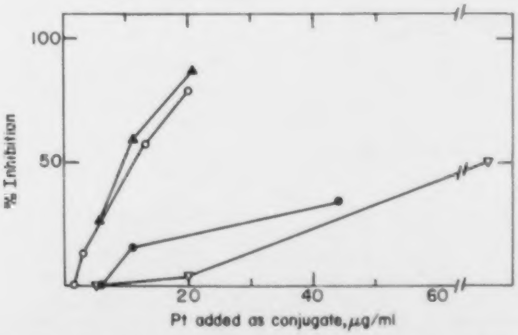


TEXT-FIGURE 3.—The inhibition of [^{3}H]dThd incorporation of YAC cells by various Pt-protein and Ig complexes: Pt-HSA (×), Pt-NGIg (●), Pt-anti-38 Ig (▼), Pt-anti-YAC (goat Ig) (△), and Pt-anti-YAC (hybridoma IgM) (○). About 10-20 molecules of Pt are associated with one molecule of Ig or HSA.

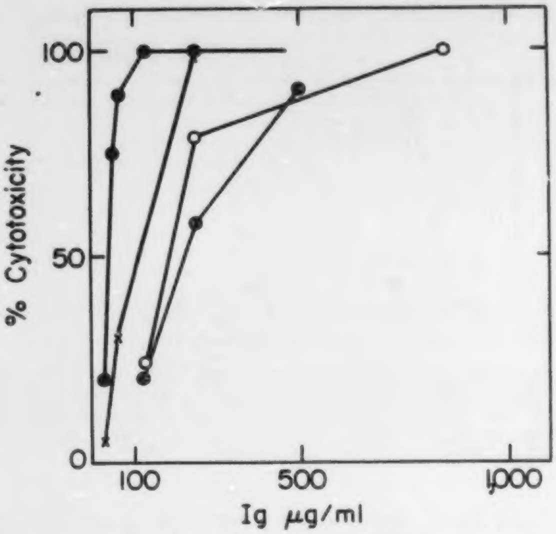
ent preparations. The coupling procedure described in "Materials and Methods" was the most efficient as judged by the resulting inhibition of [*methyl*-^{3}H]dThd uptake in vitro. Use of Ig concentrations lower than 50 mg/ml resulted in a reduction of Pt complexed to the Ig, whereas concentration of the platinate being increased during the reaction caused precipitation. The suitable length of incubation was from 2 to 3 hours, inasmuch as prolongation of the reaction time resulted in precipitation. Some precipitation also occurred upon freezing and thawing. The amount of Pt complexed to the Ig was determined by either one of the following procedures: 1) X-ray spectrography performed directly on the samples (*18*) and *2*) spectrophotometric (*19*) assay of the unbound Pt subtracted from the total. This method could not be used directly because the presence of protein interfered with the color reaction. Between 2 and 10 mol of Pt were bound per mole Ig in the different preparations.

Inhibition of DNA synthesis as measured by uptake of [*methyl*-^{3}H]dThd was used as a criterium of activity of the Pt complexes. As shown in text-figure 2, both the platinate K_2PtCl_4 and the *cis*-$(NH_3)_2PtCl_2$ similarly inhibited the uptake of [*methyl*-^{3}H]dThd by YAC cells in culture. The B-leukemia cells (38C13) were inhibited by the platinate and *cis*-DDP only at much higher concentrations than were the YAC cells.

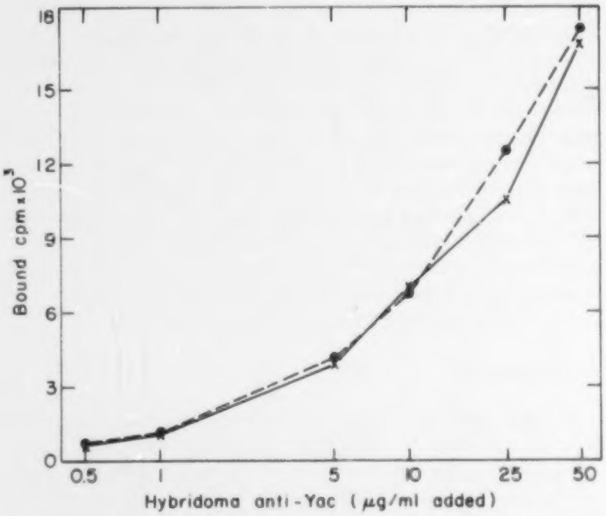
The inhibition of the Pt-Ig complexes is depicted in text-figures 3 and 4. The degree of inhibition varied somewhat with the different preparations. However, with all the preparations of antitumor reactive Ig-Pt complexes, the inhibition was stronger than could be accounted for by the amount of Pt bound to the Ig as compared to both Pt salt and *cis*-DDP. An inhibitory activity was observed also by Pt complexed to nonspecific proteins such as normal Ig and HSA but with concentrations higher than those of Pt bound to the cell reactive Ig (text-figs. 3, 4). In the B-cell leukemia 38C13, DNA synthesis was inhibited by the Pt salts, K_2PtCl_4 and *cis*-DDP, at concentrations above 50 µg/ml. Pt complexed to antibodies (anti-YAC), which were strongly reactive with the tumor cells, were effective inhibitors. Antibodies directed against the specific surface IgM of 38C13 cells (idiotypic antibodies), although capable of attaching to the cells at specific sites, were not as effective as the anti-YAC Ig that was as reactive with these tumor cells as with the YAC cell toward which it was directed originally. Perhaps the anti-YAC IgG was more effective due to its ability to attach to many sites, as seen by fluorescence studies. The inhibitions by the Pt-Ig conjugates were not reversible over 48 hours. In both systems the immune Ig by itself had no effect on the dThd incorporation.



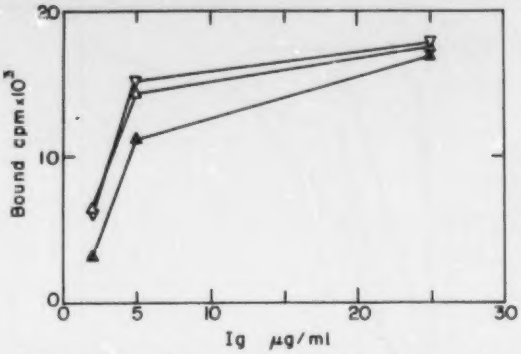
TEXT-FIGURE 4.—The inhibition of [^{3}H]dThd incorporation of leukemia 38C13 cells, by various Pt-Ig preparations: Pt-anti-YAC Ig, preparation 1 (▲); Pt-anti-YAC Ig, preparation 2 (○); Pt-anti-38 Ig (●); and Pt-NGIg (▽). About 10–12 molecules of Pt are associated with one molecule of Ig.



TEXT-FIGURE 5.—Antibody activity of Pt-anti-YAC complexes measured by complement-mediated cytotoxicity. Complement-mediated lysis of YAC cells was measured by incubation of YAC cells (5×10^5) with dilutions of anti-YAC, goat Ig, or Pt-anti-YAC complexes. Anti-YAC Ig, preparation 1 (×); anti-YAC Ig, preparation 2 (●); Pt-anti-YAC, preparation 1 (○); and Pt-anti-YAC, preparation 2 (⊗).



TEXT-FIGURE 6.—Antibody binding activity of Pt-anti-YAC IgM complexes. Antibody binding activity of a hybridoma anti-YAC IgM to YAC Formalin-fixed cells (10^5/well) was measured after its complexing with Pt. Binding activity was measured indirectly with ^{125}I-labeled goat anti-mouse $(Fab')_2$. Mouse anti-YAC IgM (●- - -●), Pt-mouse anti-YAC (x—x).



TEXT-FIGURE 7.—Antibody binding activity of Pt–anti-38 complexes. Antigen binding of Pt complexed anti-38 goat Ig was measured by a direct binding assay with the use of the ^{3}H-labeled antigen, surface IgM of leukemia 38C13 cells. Goat anti-38 Ig (▽); Pt–anti-38 Ig, preparation 1 (△); and Pt–anti-38 Ig, preparation 2 (▲).

Complement-mediated cytotoxicity by some Pt–antitumor Ig preparations was considerably diminished (text-fig. 5). While with one preparation 55% of the original activity was still maintained, in another preparation the activity dropped to 20% of the original. The decrease in complement activity may be related to the amount of Pt bound to the antibody or to the occupation by Pt of a complement site. To test whether Pt complexing affected the antibody binding capacity, the binding of antibodies to the tumor cells was assayed indirectly in the YAC system with ^{125}I-labeled goat anti-mouse (Fab′)$_2$ as a second antibody. As shown in text-figure 6, identical binding curves were obtained both with the anti-YAC and the Pt–anti-YAC; thus the binding of the hybridoma antibody IgM anti-YAC was not affected by its complexing with Pt. In the B-cell leukemia 38C13 system, the binding of Pt–anti-38 IgM idiotypic antibodies to ^{3}H-labeled IgM (*20*) was not markedly reduced by the attachment of the antibody to Pt (text-fig. 7). Thus in both systems the antigen binding capacity of the antibody was not modified by the Pt complexing.

DISCUSSION

In this study we have demonstrated that complexes formed between Pt salts and antibodies retain both the antibody activity and the DNA synthesis inhibitory activity of Pt. Moreover, the inhibitory activity was enhanced with Pt–Ig complexes in which the Ig possessed high binding affinity toward the tumor cells. The complexes between Ig and Pt were formed simply by incubation of Pt salt with the antibodies for a few hours at room temperature.

Complexes between proteins including Ig and Pt have been previously used in X-ray crystallography (*13*). In these studies the native crystal was soaked in the Pt salt. X-ray crystallography showed that Ig have six high-affinity sites and some additional low-affinity sites (*13*). The present results, which indicate an occupancy of 2–10 Pt sites, agree with those of the crystallographic studies, although we have prepared the Pt–Ig complexes in aqueous solutions.

The antigen binding capacity of the antitumor Ig is almost fully retained (text-figs. 6, 7), whereas the complement-fixing ability of these antibodies is reduced to about 20–50% of the original in different preparations (text-fig. 5). The reduction of the complement-fixing ability can be attributed to the binding of Pt to portions of the Fc receptor, thereby perhaps blocking the complement recognition site in this part of the molecule.

The mechanism of the enhanced Pt activity when bound to specific antibody has not been elucidated; yet one can speculate that for Pt to interact with DNA (*21*, *22*) it has to penetrate the cell nucleus. The antibodies may bring the Pt to the cell surface and promote the internalization of the metal through their own binding to the antigen(s) toward which they are directed. Hurwitz et al. (*23*) have previously shown that daunorubicin, which also exerts its activity in the cell nucleus, when bound covalently to antitumor antibodies can penetrate the cell in the bound form and localize in or on the cell nucleus. Another possibility is that DNA found on the surface of tumor cells, due to its higher affinity to Pt, may cause removal of Pt from the antibody–Pt complex. Still a third possibility exists in which Pt is dissociated from its antibody complex on the cell surface and enters the cell via channels for ions opened through cell stimulation by specific antibodies. Studies to determine the exact localization and mode of action of antibody–Pt complexes are now in progress.

The mechanism of the Pt antitumor activity is not fully established. In vitro Pt was shown to interact with DNA (*24*). Several in vivo studies suggested an involvement of the immune system in the promotion of Pt action (*24–26*). Immunodepressing compounds such as hydrocortisone were shown to decrease Pt potency, while immunostimulants such as zymosan were shown to increase it.

Our findings show that Pt bound to tumor cell reactive antibodies is more efficient in the inhibition of DNA synthesis than is Pt bound to normal or nonspecific Ig or than is Pt salts. An explanation is that when under an in vivo environment Pt may attach to tumor cell-surface antibodies and thereby promote its deliverance to the pertinent cells. By this view one may also explain the therapeutic efficacy of Pt doses below the cytotoxic concentrations to the tumor cells in vitro and in vivo (*27*). In vivo explorations of the effectivity of Pt–immune Ig complexes are now in progress.

Differences in Spleen Suppressor Cell Content in Rats With Progressing and Regressing Tumors[1,2,3]

Michael A. Hollingsworth[4] *and* **Donald L. Evans**[4]

ABSTRACT—Young New Zealand Black rats (<35 wk old) developed progressively growing tumors when given injections of cells from a syngeneic 3-methylcholanthrene (MCA)-induced fibrosarcoma. Spontaneous tumor regression occurred in animals more than 10 months of age. Compared to the responses of spleen cells from age-matched controls, spleen cells from rats in which tumor progression was present (progressor rats) showed decreased proliferative responses to concanavalin (Con A), phytohemagglutinin (PHA), and syngeneic MCA tumor cells. Spleen cells from rats in which the tumors had regressed (regressor rats), however, produced significant increases in proliferative responses when compared with the responses of spleen cells from age-matched controls and from progressor rats. Cell-mixing experiments implicated the presence of two spleen suppressor cell populations in progressor rats, one of which was not present in regressor rats. The unique suppressor cell found in progressor rats appeared to be specific for tumor cell-induced proliferative responses. Spleen cells from both progressor and regressor rats produced similar suppressive effects in the PHA and Con A responses of normal cells.—JNCI 1982; 69:53–58.

Spleen cells from certain tumor-bearing animals (*1, 2*) and peripheral blood lymphocytes from some humans with malignant tumors (*3*) have decreased proliferative responses to Con A and PHA. These diminished responses have been attributed to suppressor cells (*1–3*). Suppressor cells from tumor-bearing animals were effective inhibitors of tumor-specific and alloreactive cytotoxic T-lymphocytes (*4–7*), lymphoma cell proliferation (*8*), mixed leukocyte culture responses (*4, 9, 10*), lymphoproliferative responses to tumor-associated antigens (*11*), graft-versus-host reactions (*12*), and host resistance to syngeneic tumors (*13*).

In other work, whole-body irradiation inactivated a spleen-seeking suppressor cell in MC1315 tumor-bearing BALB/c mice. Tumors in these animals subsequently regressed (*14*). Reports on the effects of splenectomy of tumor-bearing animals indicated equivocal results demonstrating inhibition (*15–18*), enhancement (*19, 20*), or no effect on tumor growth (*21–23*).

We previously reported (*24*) an age-related increase in natural immunity to a syngeneic MCA-induced fibrosarcoma in New Zealand Black rats. Inoculation of tumor cells into these animals was followed by growth of palpable tumors that spontaneously regressed in animals 12–16 months of age. Tumors in younger animals did not regress. We also characterized variations in the proliferative response to PHA, Con A, and irradiated syngeneic MCA tumor cells in aging normal NBR rats. In younger animals (<52 wk old), ADH cells generated the highest Con A responses, whereas NA cells produced the highest PHA responses. The proliferative response of Unf cells by younger animals was low, possibly because of a naturally occurring suppressor cell. [*See* (*24*) for discussion.] The Con A and PHA responses of older animals did not differ significantly between NA and ADH fractions (*24*).

Observation of these age-related variations necessitated the use of age-matched sets of animals in tests to compare the responses of spleen cells from rats in which tumor progression was present (rat progressors, tumor progressors) and from rats in which the tumors had regressed (rat regressors, tumor regressors) with the responses of cells from normal controls. In the present work, spleen cells derived from MCA tumor progressors were shown to have decreased proliferative responses to Con A, PHA, and irradiated MCA tumor cells (MLTC assay) as compared to the responses of age-matched normal rats. Spleen cells from tumor progressors suppressed (in vitro) normal spleen cell proliferation responses to mitogens and tumor cells. Spleen cells from tumor regressors, however, showed no decreased reactivity to mitogens. They had greater than normal proliferative reactivity to MCA cells, and in the cell transfer experiments they did not suppress normal spleen cell responses to tumor cells, but instead enhanced the normal cells' proliferative capacity. Spleen cells from regressor rats (like those from progressor rats) were capable of suppressing the mitogen responsiveness of normal spleen cells.

MATERIALS AND METHODS

Animals.—Inbred syngeneic New Zealand Black rats (NBR Pl/Cr) were obtained from a breeding colony maintained at the Bowman Gray School of Medicine, Winston-Salem, N.C., and from the National Cancer Institute rat breeding facility at Charles River Breeding Laboratories, Inc., Wilmington, Mass.

Tumors.—The tumors used for animal injections and in the MLTC assays were derived from MCA-induced fibrosarcomas in NBR rats (*25*). MCA tumor cells were myco-

None[f]	125±68	386±85	506±38	4,577±3,209

[a] Spleen cells were Unf or were separated over nylon wool columns into NA and ADH populations. These results represent 9 independent experiments on rats 6–25 wk of age.

[b] Values are means ± SD.

[c] No stimulation of spleen cells by mitogens or tumor cells during 4 days of cultivation.

[d] Spleen cells were stimulated as indicated with Con A, PHA, or irradiated MCA tumor cells after 4 days of cultivation.

[e] Significantly different from normal ($P<0.01$).

[f] From cultures containing only RPMI-1640 medium, Con A, PHA, or irradiated MCA tumor cells.

plasma-free and negative for retroviruses. Tumor cells were passaged continuously in vitro in Dulbecco's modified Eagle's minimum essential medium, containing 10% fetal bovine serum and 50 μg gentamycin sulfate/ml (Garamycin; Schering Corporation, Kenilworth, N.J.), and the cells were buffered with sodium bicarbonate. MCA tumor cells, 5×10^6, were injected sc into young animals (aged <8 mo) to generate tumor progressors and into older animals (aged >12 mo) which subsequently developed into spontaneous tumor regressors (*24*). Tumor progressors were used in those experiments after tumor volume had reached at least 1×10^5 mm^3. Tumor regressors were used only after the tumors had completely regressed. We did not detect tumor cells in the spleens of tumor progressors or tumor regressors.

Spleen cell preparation.—Rats were exsanguinated, their spleens were aseptically removed, and single cell suspensions were obtained by pressing the spleen tissue through a 200-gauge, stainless steel mesh, tissue sieve. RPMI-1640 medium (KC Biologicals, Lenexa, Kans.) was supplemented with 10% fetal bovine serum (KC Biologicals), 25 m*M* HEPES[5] buffer, 5×10^5 2-mercaptoethanol (Calbiochem-Behring Corp., San Diego, Calif.), and nutrients [1% each of L-glutamine and other nonessential amino acids, essential amino acids, vitamins, and sodium pyruvate (Flow Laboratories, Inc., Rockville, Md.)]. Cell suspensions were pelleted (300×*g*) and depleted of erythrocytes by resuspension in Tris-ammonium chloride [9 parts 0.155 *M* NH_4Cl_3:1 part 0.170 *M* Tris (pH 7.2)].

Cells were washed and resuspended, viable cell counts were made, and cells were resuspended in RPMI-1640 medium at 5×10^6 cells/ml. These cells were designated as Unf.

Nylon wool fractionation.—Cells were fractionated over a nylon wool column (*26*). NA (T-cell-enriched) and ADH (B-cell and macrophage-enriched) cells were obtained. The Unf, NA, and ADH populations were each resuspended (5×10^6 cells/ml) in supplemented RPMI-1640 medium for use in the MLTC and mitogen-induced blastogenesis assays.

Mitogen-induced blastogenesis.—Mitogen-induced blastogenesis was performed with the use of Con A (Calbiochem-Behring Corp.) and PHA (Burroughs-Wellcome Co., Research Triangle Park, N.C.). Spleen cells, 5×10^5, were added to optimal mitogen amounts (1 μg Con A or 0.6 μg PHA) in a final volume of 200 μl RPMI-1640 medium. Triplicate cultures were incubated in microtiter plates (Costar, Data Packaging Corp., Cambridge, Mass.) and labeled with 2 μCi $[^3H]$dThd (ICN Pharmaceuticals, Inc., Irvine, Calif.) on day 4. Cultures were harvested 18 hours later by means of a microharvester (Bellco Glass, Inc., Vineland, N.J.). Samples were counted in a scintillation counter (model LS-233; Beckman Instruments, Inc., Fullerton. Calif.)

Tumor-induced blastogenesis.—Spleen cells were tested for proliferative responses to MCA tumor cells in MLTC cultures. Spleen cells, 5×10^5, were mixed with 1.25×10^4 irradiated (10,000 rad) MCA tumor cells. The cultures were incubated, labeled with $[^3H]$dThd, and harvested as described under "*Mitogen-induced blastogenesis.*"

Spleen cell reconstitutions.—NA and ADH cells from progressor or regressor rats were mixed at the indicated ratios with NA and ADH cells from normal age-matched rats (at ratios of 90% normal cells mixed with 10% tumor progressor or tumor regressor cells and 70% normal cells mixed with 30% tumor progressor or regressor cells). The mixed cells, 5×10^5, were then tested in the mitogen-induced blastogenesis and tumor cell-induced blastogenesis assays described above.

Statistical analysis.—The data were analyzed with the use of Student's *t*-test for comparison of two mean values.

RESULTS

Mitogen responses of normal, tumor progressor, and tumor regressor spleen cells.—Data in table 1 show that Unf, NA, and ADH spleen cells from rats bearing progressive MCA tumors had significantly decreased proliferative responses to Con A and PHA, as compared to the responses of age-matched controls. The Con A responses by regressor Unf and NA cells were often greater than the responses of normal cells but were not highly statistically significant ($P<0.1$) (table 2). Regressor ADH spleen cell responses to Con A and regressor NA and ADH responses to PHA were significantly greater than

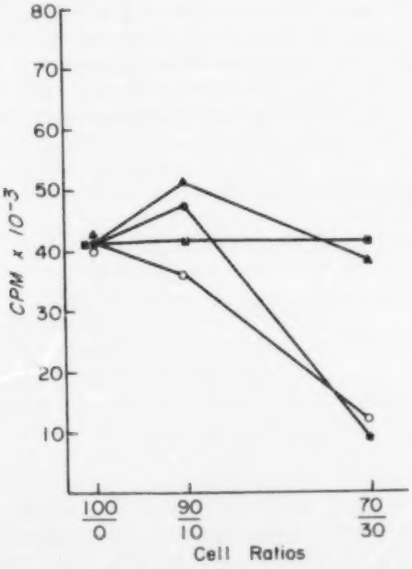
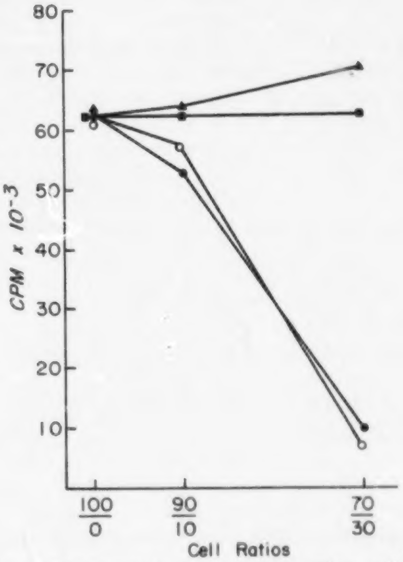
were the responses of normal spleen cell controls (table 2). Regressor Unf cell responses to PHA were variable: The responses of cells from 2 regressor rats were significantly increased, the responses of cells from another animal were not significantly different from normal, and there were three instances of significantly decreased responses, an example of which is presented in table 2.

MLTC responses.—In table 1 the proliferative responses of spleen cells from tumor progressors and age-matched normal NBR rats to irradiated syngeneic MCA tumor cells are shown. The responses of all fractions (Unf, NA, and ADH) of spleen cells from progressor rats were significantly less than those of the age-matched normal animals. The MLTC responses of regressor Unf, NA, and ADH cells (table 2) were significantly greater (6 experiments) than the responses of comparable normal cells.

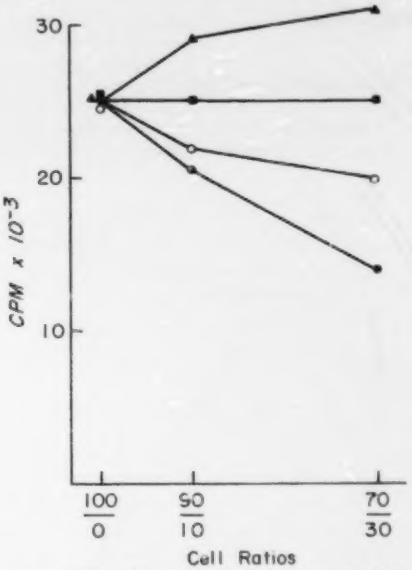


TEXT-FIGURE 1.—Normal ADH spleen cells were tested for Con A responsiveness in reconstitution assays. Different ratios of normal and tumor-bearing nylon wool fractionated spleen cells were tested. Normal and test cells (5×10^5 total cells) were mixed in cultures that consisted of 90%:10% and 70%:30% (normal cells:test cells) ratios, respectively. Mixtures were normal ADH + normal ADH control (■), normal ADH + normal NA (▲), normal ADH + tumor progressor ADH (○), and normal ADH + tumor progressor NA (●).

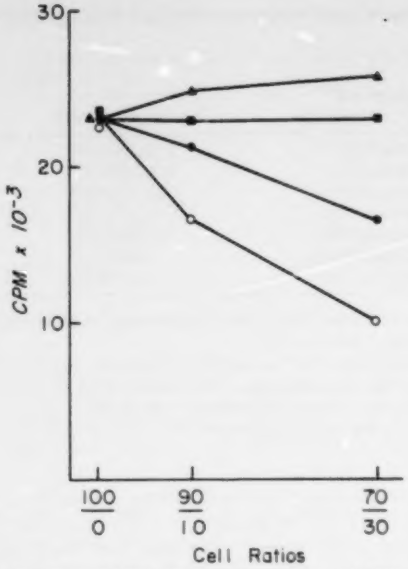


TEXT-FIGURE 2.—Determination of normal NA spleen cell responses to PHA after reconstitution (as described in text-fig. 1) with normal NA cells (■), normal ADH cells (▲), tumor progressor NA cells (○), and tumor progressor ADH cells (●).

Reconstitution experiments.—We next determined the regulatory effects of spleen cells from progressor and regressor rats by mixing spleen cells from those animals with normal rat spleen cells. Text-figure 1 shows the effect of mixing NA or ADH tumor progressor spleen cells with age-matched (15 wk) normal ADH spleen cells. [These cells were tested because they produced the highest responses to Con A (table 1)]. The addition of progressor ADH cells and of certain proportions (30%) of progressor NA cells to normal ADH cells produced a significant decrease in the proliferative responses, as compared to the values obtained after mixing different ratios of only normal cells. The same effects (significant decreases) were observed when fractionated progressor spleen cells were mixed with NA cells from normal animals and then stimulated with PHA (text-fig. 2). The addition of either progressor NA or progressor ADH cells to normal spleen cells caused a reduction in the normal proliferative responses.



Text-figure 3.—Normal NA spleen cell responses to MCA tumor cells (MLTC assay) after reconstitution with normal NA cells (■), normal ADH cells (▲), tumor progressor NA cells (○), and tumor-bearing ADH cells (●).



Text-figure 4.—Normal ADH spleen cell responses to MCA tumor cells (MLTC assay) after reconstitutions with normal ADH cells (■), normal NA cells (▲), tumor progressor ADH cells (○), and tumor progressor NA cells (●).

The responses of normal spleen cells obtained from young (13-wk-old) animals to irradiated MCA cells were similar for both NA and ADH cells (table 1). The addition of progressor NA or progressor ADH cells to normal NA cells (text-fig. 3) or to normal ADH cells (text-fig. 4) produced significantly suppressed MLTC proliferative responses by the normal cells.

Effects of regressor spleen cells on normal proliferative responses.—Table 3 shows the effects of mixing regressor spleen cells with normal cells on the proliferative responses to Con A and PHA. The addition of regressor NA cells to normal ADH cells produced a reduction in the Con A and PHA

Table 3.—*Effects of tumor regressor spleen cells on proliferative responses of normal rat spleen cells to Con A, PHA, and irradiated syngeneic MCA tumor cells*

proliferation responses of normal ADH cells (as compared to the responses in cultures containing only normal cells that were separated and remixed). Regressor NA cells produced a significant increase in the normal NA Con A response. Regressor ADH cells suppressed the normal NA and normal ADH response to both Con A and PHA.

The remixing of normal NA cells with normal ADH cells in the MLTC assay produced a decrease in the normal NA tumor cell-induced proliferative response (table 3). In similar experiments the presence of normal NA cells had little effect on normal ADH cell mitogen-induced proliferative responses. However, the addition of regressor NA spleen cells or regressor ADH spleen cells to either normal NA or normal ADH cells caused a significant increase in all normal proliferative responses to MCA cells (table 3).

DISCUSSION

We have previously shown (*24*) that NBR rats demonstrated an age-related change in susceptibility to progressive growth of a syngeneic MCA-induced fibrosarcoma. In that study we found that relatively young animals had a high incidence (>90%) of progressive tumor growth, whereas older animals had a decreased incidence of progressive tumor takes (20%) and increased incidences of regressing tumors (40%) and no tumor takes (40%).

Several investigators have previously shown decreased proliferative responses to Con A and PHA by lymphoid cells obtained from animals bearing progressively growing tumors (*1-3, 12*). We have confirmed these observations (table 1) and extended them by showing a decreased in vitro proliferative response to syngeneic MCA-induced fibrosarcoma cells in animals with progressively growing tumors (table 1). We have also shown that spontaneous regressor animals produce proliferative responses to mitogens and tumor cells that are generally greater than the responses of normal and progressor spleen cells (table 2).

The lower proliferative responses observed in progressor animals may be caused by suppressor cells (*1-12*). An alternate explanation would be that progressor animals contain fewer mitogen and tumor-reactive cells (*1*). Spleen cells from normal young animals of many different rat strains (including NBR) possess an ADH cell, the removal of which results in enhanced mitogen-induced cellular proliferation by NA cells (*1, 2, 5, 24, 27-29*). In the present study, suppressor cells from progressor rats were identified by means of reconstitution experiments. These experiments indicated that both NA and ADH spleen cells from progressor animals suppress normal spleen cell proliferative responses to Con A (text-fig. 1), PHA (text-fig. 2), and MCA tumor cells (text-figs. 3, 4). Suppression produced by tumor progressor spleen cells appears nonspecific inasmuch as it affects both mitogen and tumor cell-induced proliferative responses.

Compared to progressor rats, regressor rats had greater than normal mitogen and tumor cell-induced proliferation responses. Regressor NA spleen cell responses to PHA and to syngeneic tumor cells (table 2), and regressor ADH responses to Con A, PHA, and tumor cells (table 2), were significantly higher than were the equivalent normal spleen cell responses. When regressor spleen cells were mixed with normal spleen cells and tested in proliferation assays (table 3), regressor ADH cells suppressed normal NA and normal ADH spleen cell responses to both Con A and PHA. ADH cells from age-matched normal controls were not suppressive in similar mixing experiments. Unlike progressor NA cells, regressor NA cells enhanced the response of normal NA cells to Con A (table 3).

In general, the suppression of normal mitogen responses by regressor NA and ADH cells was similar to that caused by the same spleen cell fractions of progressor spleen cells. These data suggest that both progressive tumor growth and development of tumor immunity (regression) occur coincidentally with the generation of spleen cells that suppress normal Con A and PHA responses. The suppressive effects were greater in the progressor and regressor ADH spleen cells than in NA cells (text-fig. 2; table 3), as evidenced by the degree of suppresion exhibited by these ADH cells after mixing with normal cells.

Other investigations of rat spleen cell proliferative responses indicated that macrophages and/or prostaglandins mediate suppression (*1, 2, 4, 5, 10, 12, 16, 27*). We have previously shown (Evans DL, Hooper CJ, Johnson K: Submitted for publication) that nylon wool did not completely separate T-cells from B-cells and macrophages. NA cells contained low numbers of macrophages (3%), and ADH cells likewise contained T-cells (13%). The suppressive effect on mitogen responsiveness of cells present in progressor and regressor ADH fractions could be due to macrophages. We recently reported that Percoll density gradient centrifugation of NA and ADH cells produced enriched populations of both NA and ADH suppressor cells (*30*; Evans DL, Hooper CJ, Johnson K: Submitted for publication). The ADH suppressor cell produced significant reduction of PHA responses. This cell has a density of 1.055-1.065 g/ml and by morphological and biochemical (nonspecific, esterase-positive) criteria appears to be a macrophage. However, the NA suppression of the PHA response probably was due to a T-cell (identified by means of a monoclonal anti-T-cell antibody) of density 1.07-1.09 g/ml (*30*; Evans DL, Hooper CJ, Johnson K: Submitted for publication). Both T-cells and macrophages in normal rat spleens thus are capable of suppressing mitogen responses.

Perhaps the most important result of the cell mixing experiments was obtained when comparisons were made between the activities of regressor and progressor cells in the MLTC assays. When added to normal NA or normal ADH cells, both regressor NA and regressor ADH spleen cells produced an enhancement of the normal spleen cell responses to MCA tumor cells (table 3). Similar experiments with progressor spleen cell fractions demonstrated suppressive activities (text-figs. 3, 4) of these equivalent spleen fractions.

It is evident from these studies that more than one type of suppression is produced by spleen cells from rat progressors and regressors. Spleen cells from tumor progressor animals contain at least two suppressor populations (functions): the suppression of the normal rat mitogen and MLTC proliferative responses. Regressor spleen cells likewise have mitogen suppression activities but lack the ability to suppress normal cell responses to syngeneic tumor cells. This differential in suppresor cell function may be of considerable importance in the development of tumor immunity. Studies are currently in progress to specifically identify these different suppressor cell populations and to determine if tumor immunity in our model system is produced by a qualitative or quantitative change in these regulating cells.

Gastrin Protection Against Chemically Induced Gastric Adenocarcinomas in Wistar Rats: Histopathology of the Glandular Stomach and Incidence of Gastric Adenocarcinoma[1,2]

Masaharu Tatsuta, *M.D.*,[3] **Hisako Yamamura**, *B.S.*,[3] **Haruo Taniguchi**, *M.D.*,[4] *and* **Hiroshi Tamura**, *M.D.*[3]

ABSTRACT—The effects of gastrin on the histopathology of the glandular stomach and on the incidence of gastric carcinoma induced by *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) were investigated in inbred Wistar (W) rats. Prolonged administration of gastrin after treatment with MNNG significantly reduced the incidence of adenocarcinomas of the glandular stomach. In addition, atypical glandular proliferations were significantly less frequent and were smaller, and the incidence of marked mucosal atrophy was significantly reduced in both the antral and oxyntic gland mucosae. Both atypical glandular hyperplasia and mucosal atrophy are precursors of gastric cancers; prolonged administration of gastrin to rats after treatment with MNNG suppressed development of precursors of gastric cancer and so prevented development of gastric cancers.—JNCI 1982; 69:59–66.

Prolonged administration of gastrin to rats after treatment with MNNG significantly reduced the incidence of adenocarcinoma of the glandular stomach (*1*, *2*). It has also been reported (*3*) that hypergastrinemia in the rat after a Billroth II antral implant operation exerted a protective effect against experimental gastric carcinogenesis in that portion of the stomach remaining. Gastrin exerts a trophic influence on the gastric mucosa (*4*) and stimulates both gastric acid secretion and mucosal blood flow. These actions could decrease the suspectibility of gastric mucosa to carcinogenesis, but the exact mechanism of gastrin's effect is unknown.

In the present study, we examined gastrin's effects on the histopathology of the glandular stomach and on development of gastric adenocarcinomas by injecting gastrin in depot form into rats that had been treated with MNNG.

MATERIALS AND METHODS

Young male W inbred rats of about the same age (6 wk old) and initially weighing 100–150 g were given drinking water containing 50 μg MNNG/ml (Wako Pure Chemical Industries, Ltd., Osaka) for 25 weeks. The MNNG solution was given to rats every other day from bottles covered with aluminum foil or painted a dark color. From week 26 the rats were given ordinary tap water and divided randomly into 3 groups. Group 1 (18 rats) received no treatment; group 2 (10 rats) was given the vehicle olive oil only (0.5 ml/rat); group 3 (20 rats) was given 300 μg tetragastrin (C-terminal tetrapeptide of gastrin; Nissui Pharmaceutical Co. Ltd., Tokyo, Japan) per day as a suspension in 0.5 ml olive oil/rat. From the beginning of week 26 to the end of week 29, the rats in groups 2 and 3 were given one injection a day; then from week 30 to the end of the experiment, they were given one injection every other day. All injections were given sc between 2 and 3 p.m. at a different site each time.

Animals that survived for more than week 35 were included in the effective numbers. Rats were killed when they became moribund, and those that died or were killed during the experimental period were autopsied. The stomach was fixed with a 10% neutralized Formalin solution for histologic examination. Tissues were embedded in paraffin and stained with H & E.

Histologically, adenocarcinomas were defined as lesions in which neoplastic glands had penetrated the muscularis mucosa to involve the submucosa and occasionally such deeper layers as the muscle coat, serosa, and peritoneal tissues. Cancers of the glandular stomach were classified as follows (*2*):

1) Highly differentiated adenocarcinoma: Adenocarcinoma showing atypical glandular structure with a tubular or papillary pattern and an arrangement of cells comparable to that enclosing normal gastrointestinal crypts, but adenocarcinoma in which these glands involved the muscularis mucosa (fig. 1A).
2) Well-differentiated adenocarcinomas: *a*) common type—less highly differentiated glands, consisting of disorderly masses of atypical cells containing a small amount of intracellular mucin (fig. 1B); *b*) mucinous carcinoma—active mucin secretion, often resulting in mucinous nodules with a large amount of extracellular mucin, with only a few isolated groups of tumor cells (fig. 1C).
3) Poorly differentiated adenocarcinomas: *a*) Anaplastic carcinoma—highly anaplastic cells scattered individually without any typical glandular or tubular differentiation; *b*) signet-ring cell carcinoma—tumor cells with large amounts of intracellular mucin, giving the cells a signet-ring appearance (fig. 1D).

A lesion in which the constituent cells of the gland stained hyperchromatically, the course and the size of the glands were irregular, and the nuclei were pleomorphic was called "atypical glandular hyperplasia" when it was confined to the mucosa with no penetration through the muscularis mucosa. Atypical glandular hyperplasia was classified into three grades according to severity: 1) mild—slight, irregular glandular proliferation with little or no cellular atypism resulting from a response to injury of the mucosa caused by

TABLE 1.—*Incidence of gastric cancer in MNNG-treated rats*

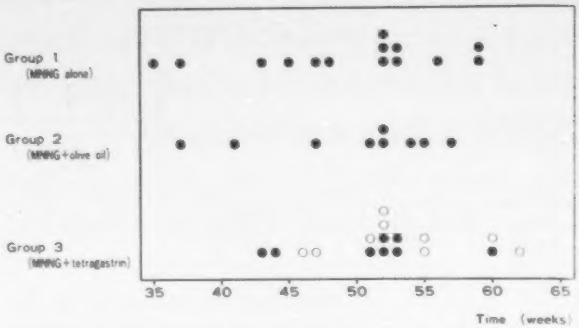
Group No. and treatment	No. of effective rats	No. (%) of rats with gastric cancer
1. MNNG alone[a]	14	14 (100)
2. MNNG + olive oil[b]	9	9 (100)
3. MNNG + tetragastrin[c]	17	8 (47.1)[d]

[a] 50 μg MNNG/ml was given in the drinking water for 25 wk.

[b] 0.5 ml of olive oil was administered to rats after exposure to 50 μg MNNG/ml for 25 wk.

[c] 300 μg of tetragastrin in depot form was administered to rats after exposure to 50 μg MNNG/ml for 25 wk.

[d] Differences between values for groups 1 and 3 and values for groups 2 and 3 were statistically significant ($P<0.05$; $P<0.01$).



TEXT-FIGURE 1.—Incidence of gastric cancers in the glandular stomach of MNNG-treated rats after 35 experimental wk. For explanation of treatment, *see* table 1. ○=no tumor; ●=adenocarcinoma.

the carcinogen (figs. 2, 3); 2) moderate—moderately irregular glandular proliferation with cellular atypism (fig. 4); and 3) severe—marked irregular epithelial proliferation with remarkable cellular and structural atypism limited to the glandular epithelium (fig. 5). The severe grade type can be equated with intramucosal carcinoma in the human stomach.

Mucosal atrophy of the antral mucosa was classified as follows: 1) mild atrophy—little or no change in the antral mucosal gland, but sometimes superficial inflammatory infiltration, edema, and epithelial damage apparent; 2) mild atrophy with overgrowth of foveolar layer—irregular overgrowth of the tubules of the superficial zone of epithelium with a variable degree of cystic changes and nearly always many glands of the deep zone remaining, which, however, show mild atrophic change; 3) moderate atrophy—marked disappearance of the antral mucosal glands; and 4) severe—usually complete disappearance of antral mucosal glands.

The height of the fundic mucosa was estimated in the central portion of the anterior and posterior walls on histologic sections cut at right angles to the surface of the mucosa. The mean of six readings, three from each portion of the anterior and posterior walls, was taken for each stomach.

The results were analyzed by the chi-square test (*5*) or Fisher's exact probability test (*6*). "Significant" indicates a calculated *P*-value of less than 0.05.

RESULTS

Incidence of gastric cancers.—The incidence of gastric cancer in each group is summarized in table 1 and text-figure 1. Among rat groups 1, 2, and 3, a total of 4, 1, and 3 rats, respectively, died before week 35 either of respiratory infection or of wasting. No tumors were found in any of these animals, which were excluded from the effective numbers.

All rats examined in group 1 (treated with MNNG alone) and in group 2 (treated with MNNG and then olive oil) had gastric cancers. The incidence of gastric cancer in group 3 (treated with MNNG and then tetragastrin) was significantly less than that in groups 1 and 2. All tumors were found in the antrum in all groups.

No gastric cancer was found in 5 rats treated with MNNG and killed at week 25.

Histologic types of adenocarcinomas.—Table 2 shows the distribution of the histologic types of adenocarcinoma among 14 group 1 rats, 9 group 2 rats, and 13 group 3 rats. Histologically, all experimentally induced tumors in the glandular stomach were adenocarcinomas. Highly differentiated adenocarcinomas were found in all rats in group 1 and in group 2. In group 3 the incidence of highly differentiated adenocarcinomas was only 37.5%, the other tumors being adenocarcinomas with little or no glandular structure. A signet-ring cell carcinoma was seen in 1 group 3 rat (12.5%). The differences between the incidences of highly differentiated adenocarcinoma in groups 1 and 3 and in groups 2 and 3 were statistically significant.

Histopathology of oxyntic gland mucosa.—The effects of tetragastrin on the oxyntic gland mucosa are summarized in tables 3 and 4. Differences were significant between the control groups (groups 1, 2, and 4) and the tetragastrin-treated group (group 3), with respect to the height of the oxyntic gland mucosa and the incidence of atypical glandular hyperplasia. In group 1 and in group 2, mucosal atrophy was remarkable in the oxyntic gland area, but

TABLE 2.—*Histologic types of adenocarcinomas in glandular stomach of MNNG-treated rats*

Group No. and treatment[a]	No. of effective rats	No. of rats with adenocarcinoma	No. (%) of rats with highly differentiated adenocarcinoma	No. (%) of rats with well-differentiated adenocarcinoma of:		No. (%) of rats with poorly differentiated	
				Common type	Mucinous type	Signet-ring cell carcinoma	Anaplastic carcinoma
1. MNNG alone	14	14	14 (100)	0	0	0	0
2. MNNG + olive oil	9	9	9 (100)	0	0	0	0
3. MNNG + tetragastrin	13	8	3 (37.5)[b]	3 (37.5)	1 (12.5)	1 (12.5)	0

[a] For explanation of treatment, *see* table 1.

[b] Differences between the incidences of highly differentiated adenocarcinomas in groups 1 and 3 and incidences in groups 2 and 3 were statistically significant ($P<0.005$; $P<0.01$).

TABLE 3.—*Mucosal height of the oxyntic gland area in MNNG-treated rats*

Group No. and treatment[a]	Mucosal height in mm, mean ± SE
1. MNNG alone	0.42±0.02
2. MNNG + olive oil	0.43±0.02
3. MNNG + tetragastrin	0.73±0.02[b]
4. No treatment	0.65±0.03[c]

[a] For explanation of treatment, *see* table 1. No treatment: Rats were given ordinary tap water throughout the experimental period and killed at wk 52.

[b] Differences between values in groups 1 and 3 and values in groups 2 and 3 were statistically significant ($P<0.001$; $P<0.001$).

[c] Differences between values in groups 1 and 4 and values in groups 2 and 4 were statistically significant ($P<0.001$).

administration of tetragastrin after treatment with MNNG for 25 weeks resulted in a significant increase in the height of the fundic mucosa in group 3. Atypical glandular hyperplasia was found in groups 1, 2, and 3 less frequently and was less marked in oxyntic gland mucosa than that in the antral gland mucosa. No severe or moderate atypical glandular hyperplasia was seen in the oxyntic mucosa in any of the groups, and mild atypical glandular hyperplasia was found less frequently in group 3 rats than in the control groups 1 and 2.

Histopathology of antral gland mucosa.—The effects of tetragastrin on the antral mucosa are summarized in tables 5 and 6. Mucosal atrophy was marked in the antral mucosa in group 1 treated with MNNG only and in group 2 treated with MNNG and then olive oil. In group 3 treated with MNNG and then tetragastrin, the incidence of mucosal atrophy of moderate or severe grade was less frequent. The differences between the incidences of marked mucosal atrophy in groups 1 and 3 were statistically significant. Atypical glandular hyperplasias of various grades were frequent in the antrums of groups 1 and 2. Prolonged administration of tetragastrin after MNNG treatment in group 3 significantly decreased the incidences of atypical glandular hyperplasias of moderate or severe grade in the antral mucosa. The incidence of mild atypical glandular hyperplasia was also decreased by tetragastrin treatment: The differences between the values in groups 2 and 3 were statistically significant, but those between the values in groups 1 and 3 were not.

TABLE 4.—*Incidence of atypical glandular hyperplasia in oxyntic gland mucosa of MNNG-treated rats*

Group No. and treatment[a]	No. of effective rats	No. (%) of rats with atypical glandular hyperplasia		
		Mild	Moderate	Severe
1. MNNG alone	14	7 (50.0)	0	0
2. MNNG + olive oil	9	5 (55.6)	0	0
3. MNNG + tetragastrin	17	1 (5.9)[b]	0	0

[a] For explanation of treatment, *see* table 1.

[b] Differences between values in groups 1 and 3 and values in groups 2 and 3 were statistically significant ($P<0.02$; $P<0.01$).

DISCUSSION

In 1967 Sugimura and Fujimura (*7*) reported that when MNNG was given to rats in their drinking water, adenocarcinomas of the glandular stomach developed at a high incidence within 1 year. Gastric acid secretion decreased during cancer development in rats treated in this way, as it does during development of gastric cancer in humans (*8*). These findings suggested that MNNG may be useful in studies of the pathogenesis and pathophysiology of gastric cancer.

The sequential morphologic changes in the stomach during carcinogenesis were investigated in rats (*8-11*), hamsters (*12*), and dogs (*13-15*) to elucidate precursors of gastric carcinoma. In rats, Saito et al. (*9*) showed the following

TABLE 6.—*Incidence of atypical glandular hyperplasia in antral mucosa of MNNG-treated rats*

Group No. and treatment[a]	No. of effective rats	No. (%) of rats with atypical glandular hyperplasia		
		Mild	Moderate	Severe
1. MNNG alone	14	7 (50.0)	9 (64.3)	8 (57.1)
2. MNNG + olive oil	9	6 (66.7)	6 (66.7)	7 (77.8)
3. MNNG + tetragastrin	17	3 (17.3)[b]	3 (17.6)[c]	2 (11.8)[d]

[a] For explanation of treatment, *see* table 1.

[b] Differences between values in groups 2 and 3 were statistically significant ($P<0.02$), but differences between values of groups 1 and 3 were not.

[c] Differences between values in groups 1 and 3 and values in groups 2 and 3 were statistically significant ($P<0.05$; $P<0.02$).

[d] Differences between values in groups 1 and 3 and values in groups 2 and 3 were statistically significant ($P<0.02$; $P<0.002$).

TABLE 5.—*Incidence of mucosal atrophy in antral mucosae of MNNG-treated rats*

Group No. and treatment[a]	No. of effective rats	No. (%) of rats with:			
		Mild atrophy with overgrowth of foveolar layer	Mild atrophy	Moderate atrophy	Severe atrophy
1. MNNG alone	14	3 (21.4)	0	5 (35.7)	6 (42.9)
2. MNNG + olive oil	9	1 (11.2)	0	4 (44.4)	4 (44.4)
3. MNNG + tetragastrin	17	4 (23.5)	7 (41.2)	5 (29.4)	1 (5.9)

[a] For explanation of treatment, *see* table 1. For comparison of the incidence of moderate and severe atrophy in groups 1 and 3, the chi-square test was used. For this analysis the four grades of the mucosal atrophy were contracted to two, namely, mild atrophy with and without overgrowth of foveolar layer versus moderate and severe atrophy. The differences in groups 1 and 3 were statistically significant, but differences between those in groups 2 and 3 were not significant.

changes: first erosion and shallow ulcer formation, then regenerative glandular hyperplasia following adenomatous hyperplasia, and finally development of adenocarcinoma. Bralow et al. (*8*) reported that histologic changes occurred in rats within 3 days of exposure and consisted of submucosal edema, eosinophilic infiltration, and an increase in the lamina propria. By the 28th week, a marked increase in the thickness of the lamina propria, pinching of the basal portion of the glands, and formation of microcysts were observed, but no mucosal ulceration, glandular atypism, or significant areas of mucosal atrophy were seen. However, at week 52 of treatment with MNNG, extensive changes were found in the mucosa with areas of atrophy, glandular atypism, intestinal metaplasia, and microcyst formation.

Gastric atrophy may be a precursor of gastric cancer induced by MNNG in rat stomach, because the main site of development of both atrophy and tumor formation in rats treated with MNNG appears to be the antrum. Mucosal atrophy involved the antral mucosa more than the fundal area (*8*, *10*). Mucosal atrophy resulted from injury to the generative cell zone by MNNG (*11*), and it was the end result of erosion or superficial erosive changes.

Glandular atypism or atypical glands may also be precursors of gastric cancer in rats. Shirai (*10*) reported that the appearance of atypical glands and sometimes glandular hyperplasia in the pyloric mucosa were important early changes in carcinogenesis of the glandular stomach of the rat. The atypical glands that developed after week 16 often invaded the submucosa. This appearance of atypical glands showing submucosal growth seemed to be the initial carcinogenic change in the gastric mucosa. Saito et al. (*9*) reported that after atrophy and erosion of the mucosa, regenerative glandular hyperplasia (i.e., irregular glandular proliferation) developed at the margin of the erosions in weeks 3–5 and that these lesions persisted for the rest of the experiment. This type of proliferation is considered to be a reaction to injury of the mucosa caused by MNNG, but the possibility that it is an initial step in cancer development cannot be disregarded.

In dogs (*14*), about half of the experimentally induced gastric cancers developed from an active or a healed ulcer. In rats, erosion and/or ulceration of the mucosa acquired importance as a chance for carcinogenesis during repetition of mucosal damage and repair (*9*). However, in our study and the study of Shirai (*10*) there were few erosions, because the concentration of the carcinogen was low. Therefore, we conclude that erosion is not necessary for MNNG gastric carcinogenesis in rats.

Human cancers frequently originate from areas of intestinal metaplasia in the stomach. Moreover, intestinal metaplasia is often observed in countries where stomach cancer is common (*16*). There are many reports of a close correlation between intestinal metaplasia and adenocarcinoma of the stomach, especially carcinoma of the well-differentiated type (*17*, *18*). During gastric carcinogenesis of the glandular stomach of the rat, intestinal metaplasia has been detected (*15*, *19*). However, in the present study no intestinal metaplasia was observed, so our experiment provides no information on the relationship between intestinal metaplasia and development of MNNG-induced gastric cancer.

The present results show that administration of tetragastrin in depot form after MNNG treatment for 25 weeks reduced the incidence of gastric cancer in the glandular stomach of the rat. Moreover, gastrin suppressed the development of mucosal atrophy and atypical glandular hyperplasia, which are considered precursors of gastric cancer in rats. Therefore, gastrin most likely suppresses development of precursors of gastric cancer and so prevents the development of gastric cancer.

Gastrin exerts a trophic influence on the gastric mucosa and stimulates gastric acid secretion and mucosal blood flow. These actions may be related to the reduced incidence of gastric cancer, but the exact mechanism of the effect of gastrin is unknown and needs further study.

Subcutaneously Injected Radiolabeled Liposomes: Transport to the Lymph Nodes in Mice[1,2]

Vasily I. Kaledin,[3] Nellie A. Matienko,[3] Valery P. Nikolin,[3] Yevgeny V. Gruntenko,[3] Vladimir G. Budker,[4] *and* **Tamara E. Vakhrusheva[4,5]**

ABSTRACT—Male A/He mice were given sc injections in the feet with [3,5,3′-^{125}I]triiodothyronine, [^{125}I]T$_3$, either in the free state or encapsulated within sonicated phosphatidylcholine liposomes. Radioactivity was recovered from the injection site, the popliteal lymph nodes (LN), blood, liver, lungs, and spleen at various times (5 min to 6 hr) after injection. The highest level of radioactivity was found in the popliteal LN of mice given liposome-encapsulated (LE) [^{125}I]T$_3$: For more than 3 hours after the injection, radioactivity was fivefold to fiftyfold higher there than that in all the other organs including the popliteal LN of mice given injections of free [^{125}I]T$_3$. The results demonstrated that sc injected liposomes enter the lymphatic pathways and reach the draining LN. Thus local administration of LE antitumor drugs into the sites of a malignant tumor before its excision might be useful in preventing postoperative metastases to the draining LN.—JNCI 1982; 69:67–71.

In a previous paper (*1*), we suggested that liposomes, when administered into a lymphatic vessel, can reach the regional LN and remain there as corpuscular bodies. We attempted to use this approach to deliver antitumor agents to LN with tumor metastases (*2*). The available model, i.e., mice with metastatic tumors in the popliteal LN, however, was not suitable for the direct injection of drug-containing liposomes into a lymphatic vessel. In view of the known high permeability of the endothelial walls of lymph capillaries to particulate and colloid material (*3*), we injected LE antitumor agents, *cis*-diamminedichloroplatinum(II) or hydrocortisone, sc into mouse feet with primary tumors with the expectation that some portion of the drug-carrying liposomes would enter the lymphatic channels and, ultimately, the metastatically affected popliteal LN. Although the results indicated that when this mode of administration was used, the drug exerted an antimetastatic effect in the LE but not in the free form (*1, 2*) and thus lent credibility to our assumption, experiments were needed to demonstrate that liposomes injected into tissues do enter the lymphatic vessels and reach the draining LN. To our knowledge, only a few reports in the literature deal with this problem (*4, 5*). If our assumptions are correct, the interstitial administration of drug-containing liposomes into a tumor site would ensure the entrance of the drug into the whole set of draining LN to which the metastatic cells can spread. This route of administration would eliminate the need for the difficult and often impracticable method of direct injection of liposomes into each lymphatic vessel leading to the regional LN.

This study was designed to trace the distribution of radioactivity in the draining LN and other organs of mice after sc injection into the feet of LE or free radiolabel. The results demonstrated that in mice given injections of LE [^{125}I]T$_3$, the amount of radioactivity per gram of tissue in the popliteal LN was over tenfold higher than that in other organs and that in the popliteal LN of control mice given free [^{125}I]T$_3$.

MATERIALS AND METHODS

Mice.—Male 10-week-old inbred A/HeJ mice were used that were bred in the vivarium of the Institute of Cytology and Genetics of the Siberian Branch of the U.S.S.R. Academy of Sciences. The animals were kept in metal cages and had free access to food and water.

Liposomes.—Liposomes were prepared from egg yolk phosphatidylcholine as previously described (*2*). We prepared an emulsion with 30 mg of the lipid in 1.5 ml of a 0.14-*M* NaCl solution containing 2 mCi [^{125}I]T$_3$ (sp act, 1 Ci/mmol); Radiochemical Centre, Amersham, Buckinghamshire, England). The mixture was sonicated (22 kHz and 0.16 amp.) five times for 1 minute with 0.5-minute intervals at 0°C. Nonencapsulated [^{125}I]T$_3$ was removed from the liposomes by gel filtration through a Sephadex G-50 column (Pharmacia Chemicals, Uppsala, Sweden). The average size of liposomal vesicles prepared in this manner has been shown to be 430±17 Å (*2*). Approximately 1.5% of the original radioactivity was entrapped within the liposomes. The radioactivity of 1 ml of the liposome suspension containing 20 mg phosphatidylcholine was about 4.0×10^7 cpm. The label remained vesicle bound after incubation of the labeled liposomes for 3 hours at 25°C. The liposome suspension was diluted with saline to a final concentration of about 3 mg of the lipid per ml (6.15×10^6 cpm). A solution of free [^{125}I]T$_3$ at the same concentration was used in the control experiments.

Treatment.—Mice received 0.1 ml sc injections of the liposome suspension or a solution of free [^{125}I]T$_3$ into the region of the plantar aponeurosis (0.05 ml into each foot). The total dose of radioactivity was 6.15×10^5 cpm per mouse. The mice were decapitated at fixed times, and blood samples were collected. The popliteal LN were dissected, and the

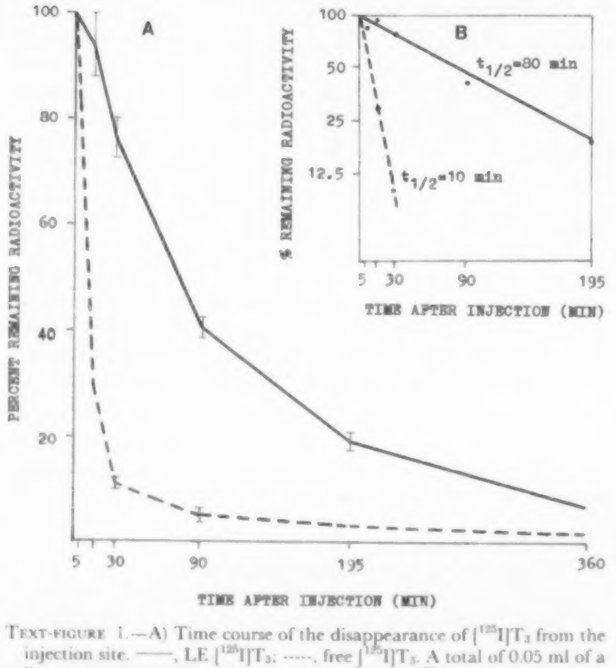
feet were amputated above the ankle joint. In some experimental groups, the liver, lungs, and spleen were removed and weighed. Radioactivity was registered in a counter (Minigamma model; LKB Producter AB., Bromma, Sweden). The sum of counts of both feet and that of both popliteal LN of each mouse were determined. For calculation of the amount of radioactivity per gram of tissue, the weight of the popliteal LN was taken as 2 mg (1 mg for each node). The data were tested by Student's *t*-test for statistical significance.

RESULTS

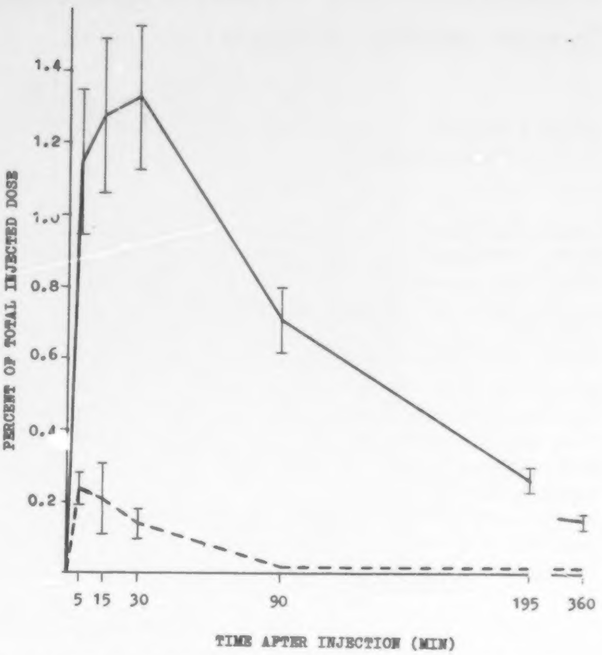
Recovery of Radioactivity From the Injection Site, Popliteal LN, and Blood

Injection site.—The patterns of radioactivity recovered from the feet after injection of free or LE [^{125}I]T$_3$ varied considerably (text-fig. 1A, 1B). Free [^{125}I]T$_3$ was removed rapidly from the injection site; the feet retained only 30% of the label 15 minutes after injection and virtually none 1.5 hours after injection. Half-time of the label removal was estimated to be 10 minutes (text-fig. 1B). LE [^{125}I]T$_3$ remained longer at the injection site; 15 minutes after injection more than 90% of the label was still in the feet and at 1.5 hours as much as 40% of the radioactivity could still be recovered from the injection site. The half-life of the [^{125}I]T$_3$ removal from the feet was 80 minutes (test-fig. 1B).

Popliteal LN.—In mice treated with free [^{125}I]T$_3$, the popliteal LN showed the highest radioactivity (0.24% of the total amount administered) 5 minutes after the injection (text-fig. 2). The radioactivity level subsequently decreased, and it reached the base value at 1.5 hours. In mice inoculated with LE [^{125}I]T$_3$, the radioactivity recovered from the LN 5 minutes after injection was fivefold higher than that in control mice. The level of nodal radioactivity in these mice rose during the next 25 minutes and reached maximum value (1.34% of the injected dose) at 30 minutes. Radioactivity decreased steadily thereafter, and at 3 hours it approached the 0.27% level which was the highest level in controls given free [^{125}I]T$_3$.



TEXT-FIGURE 1.—A) Time course of the disappearance of [^{125}I]T$_3$ from the injection site. ——, LE [^{125}I]T$_3$; -----, free [^{125}I]T$_3$. A total of 0.05 ml of a liposome suspension containing 6.15×10^6 cpm [^{125}I]T$_3$/ml or the same amount of free [^{125}I]T$_3$ was injected into each mouse foot. *Each point* represents the sum of counts in both feet (mean ± SE) of 4–6 animals. B) Apparent half-life ($t_{1/2}$) of radioactivity removal from the injection site in experimental and control mice. Values are taken from the experiment presented in A.



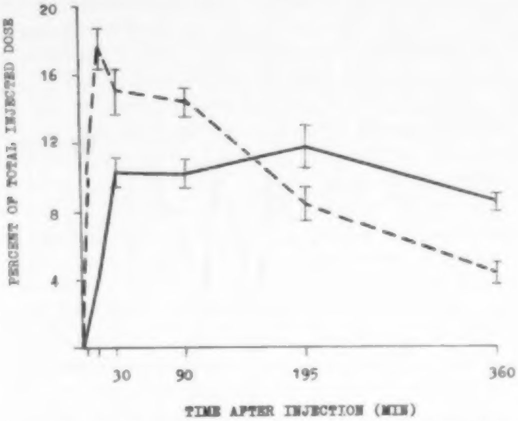
TEXT-FIGURE 2.—Radioactivity recovered from the popliteal LN of mice given sc injections of [^{125}I]T$_3$ into the feet. ——, LE [^{125}I]T$_3$; -----, free [^{125}I]T$_3$. For details *see* text-fig. 1.

Whole blood.—The recovery rates of free or LE [^{125}I]T$_3$ from the whole blood of experimental and control mice are presented in text-figure 3. Radioactivity rapidly appeared in the blood of mice given free [^{125}I]T$_3$. The recovery rate reached a maximum level 15 minutes after injection, but it decreased by half at 3 hours. In contrast, LE [^{125}I]T$_3$ entered the bloodstream much more slowly; however, after it reached a blood radioactivity level of about half of the highest control level, it remained fairly constant throughout the experiment.

Relative Radioactivities in the Blood, Popliteal LN, and Other Organs

Data for radioactivities in the blood, popliteal LN, liver, lungs, and spleen, calculated per gram of tissue (relative radioactivity) at various times after administration of LE or free [^{125}I]T$_3$, are summarized in table 1. The highest level of relative radioactivity was observed in the popliteal LN of mice given LE [^{125}I]T$_3$; for over 3 hours after injection, radioactivity was fivefold to fiftyfold higher than that in any other organs of the experimental or control mice.

Results were significantly different for the group that received free [^{125}I]T$_3$. In this group, the radioactivity of the popliteal LN exceeded that of the blood by eighteenfold at 5 minutes and fivefold at 30 minutes after injection. However, at 1.5 hours, there was no difference in radioactive label concentration between the LN and the blood. Relative radioactivity in the liver, lungs, and spleen was at about the same level as that of the blood. Similarly, in the group given LE [^{125}I]T$_3$, the concentration of the isotope in the organs was not appreciably higher than that in the blood. Thus even in the liver, an organ outstanding in its capacity to sequester liposomes, label concentration was only three to four times higher than that in the blood.



TEXT-FIGURE 3.—Radioactivity recovered from the whole blood of mice after sc injection of [^{125}I]T$_3$ as described in legend of text-fig. 1. ——, LE [^{125}I]T$_3$; -----, free [^{125}I]T$_3$. The experimentally obtained counts were adjusted to 1.6 ml, the average total blood volume of a mouse (7% of body wt.).

DISCUSSION

The results indicate that after sc injection into the feet of mice, free [^{125}I]T$_3$ is rapidly removed from the injected site. The early appearance of radioactivity in the blood indicates that free [^{125}I]T$_3$ passes easily through the capillary walls and is carried away by the bloodstream. A portion of the injected [^{125}I]T$_3$ penetrates the lymphatic capillaries, but because blood flows much faster than lymph, the major bulk of the hormone is removed with the circulating blood and only a small portion passes through the regional LN with the lymph. Thus from 5 to 15 minutes after injection of free [^{125}I]T$_3$, 50% of the isotope was removed from the feet, whereas not more than 0.25% of it was present in the popliteal LN. LE [^{125}I]T$_3$ was removed from the injection site almost tenfold more slowly than the free label. Radioactivity appeared in the blood later and in smaller amounts in these mice than in those given free [^{125}I]T$_3$. In contrast, the label was found early and in high quantities in the draining LN. During the same 10 minutes (5–15 min after injection), in mice given LE [^{125}I]T$_3$, approximately 6% of

the label was removed and about a quarter of this quantity was recovered from the popliteal LN. At an earlier time 5 minutes after injection, almost half of the isotope removed from the feet was present in the LN. These results, along with data in the literature (*4, 6–8*), demonstrate that liposomes, like particulate matter and colloids (*3*), are absorbed from tissues predominantly, if not exclusively, by lymphatic capillaries rather than by blood capillaries; hence the lymphatic system is presumably the sole pathway through which liposomes are transported from the injection site.

Obviously, the passage of liposomes along this pathway is slow, and their concentration is high as long as they remain at the injection site. Consequently, the high radioactivity recovered from the popliteal LN of mice given injections of LE [^{125}I]T$_3$ might have been due merely to the passage of lymph carrying large amounts of labeled liposomes through the LN. Was this the only reason for the high recovery rate, or were the liposomes in some way retained by the nodes? The observation that the radioactivity level in the LN of mice given LE [^{125}I]T$_3$ kept rising for at least 30 minutes after injection favors the idea of liposome retention. However, as shown in table 1, the group given injections of LE [^{125}I]T$_3$ had more than three times higher radioactivity in the liver compared with that in the blood, whereas the group that received free [^{125}I]T$_3$ exhibited no difference in the relative radioactivities in the liver and blood. The liver is known to be the major organ site where the iv injected liposomes are accumulated (*9, 10*). Hence, although the administration route we employed precluded a direct entry of the liposomes into the blood, a certain proportion of them still gained access to the general circulation. This phenomenon may be attributed either 1) to the ability of a certain proportion of liposomes to pass unhampered through the LN or 2) to the clogging of lymphatic sinuses by liposomal vesicles and the entrance of others into the general circulation through pathways that bypass the obstructed LN.

If the second assumption were true, the relationship between label concentration in the LN and the dose of inoculated liposomes would not be linear. To test this assumption, we performed an experiment in which we injected into the feet of mice a liposome suspension diluted threefold, sixfold, and twelvefold with saline. The radioactivity recovered from the popliteal LN of these mice was directly related to the dose of liposomes injected; as a result, the percentage of radioactivity in the LN was consistently the same at all doses employed (table 2). The results of this experiment indicate that sonicated liposomes do not obstruct mechanically the lymphatic sinuses in the LN. Instead, the movement of the liposomes in the LN is decelerated by the slowing of the lymph flow and by the multiple collisions of liposomal vesicles with the nodal reticulum meshwork. Because there are lymph-borne metastasizing tumor cells anchored in areas where liposomes pass through the LN, contact with these cells is inevitable. Direct contact with tumor cells is crucial for the tumoricidal effectiveness of drug-containing liposomes (*2, 11, 12*).

TABLE 2.—*Radioactivity recovered from the popliteal LN of mice that received different doses of LE [^{125}I]T$_3$ sc in the feet*[a]

Time after injection, min	Percentage of radioactivity recovered after liposome dose of:[b]			
	0.025	0.05	0.1	0.3
15	1.51	1.07	1.01	1.28
30	1.64	1.34	1.66	1.34

[a] Data are expressed as percentage of the injected dose (mean of 4 mice).

[b] Dose is expressed as mg of lipid per mouse.

It was shown that "solid" liposomes, liposomes prepared from lipids whose temperature of phase transition is above body temperature, fuse poorly, if at all, with cells, and the agent encapsulated in them is delivered to the cells mainly by phagocytosis of liposomal vesicles (*13–15*). Solid liposomes presumably can exert an antimetastatic effect on phagocytizing tumor cells only. It is unlikely that the phagocytic activity of tumor cells would be higher than that of macrophages; thus macrophages in the LN should be more vulnerable to the action of solid liposomes than tumor cells. Liposomes prepared from lipids whose point of phase transition is below body temperature ("fluid" liposomes) can fuse with both normal and malignant cells (*13–15*). Consequently, the cytotoxic action of drugs entrapped in fluid liposomes on tumor cells which they encounter as they traverse the lymphatic sinuses is surely not weaker than that exerted on normal cells of the LN.

Both solid and fluid stable liposomes that do not interact with cells in the LN, apparently pass through LN and ultimately enter the bloodstream. Entrance of undegraded liposomes absorbed by lymphatic capillaries from the abdominal cavity into the blood is now well documented (*7, 8*). Hence, when stable liposomes are used as drug vehicles, only a portion of the drug reaching an LN can exert its cytotoxic action. Fluid liposomes from biogenic lipids, which do not contain cholesterol, are unstable in body fluids (*7, 16*). The longer such liposomes stay in an LN, the larger is the number of vesicles destroyed that are not fused with cells and not subjected to phagocytosis; moreover, the released drug has a chance to exert its cytotoxic action in the LN before it enters the general circulation. Therefore, there are grounds for the assumption that it is precisely the unstable fluid liposomes that would affect metastatic growth spreading by the lymphatic pathways more efficiently than the stable liposomes. This phenomenon is apparent when a LE drug is administered directly into a lymphatic vessel. With regard to the local injection of liposomes into tissues, the question may be raised whether unstable liposomes are less effective than stable ones, since a portion of the unstable vesicles is possibly degraded before entering the lymphatic vessels. However, this theory may not be the case: Liposomes devoid of cholesterol are unstable in body fluid only but not in saline (*7*) in which they are suspended and remain long enough at the injection site. Further experiments are needed to clarify this point. Experiments are also needed to determine the differential characteristics of the lymphatic absorption of injected unilamellar and multilamellar liposomes from the tissue and their passage through LN.

Tumor sites are drained by a network of lymphatic vessels and numerous LN, and none is secure against metastatic spread. To be reasonably certain that metastatic spread is prevented, one has to deliver an antitumor agent to each draining LN. In the case of even a superficial cancerous growth (e.g., mammary tumor), the direct administration of an antitumor agent into each lymphatic vessel is a formidable task. It can be done, however, by the local injection of the LE drug into tissues in the region where the tumor is located. The present work, along with results previously published (*4*, *5*), demonstrates that this approach provides a high concentration of the drug in the draining LN and, as has been demonstrated in our previous paper (*2*), a strong antimetastatic action. Our results support the idea that liposomes could be used as vehicles of choice for transport of scintigraphic agents (*4*) and X-ray contrast media to the lymphatic pathways in indirect lymphography.

Prophylactic and Therapeutic Actions of Supplemental β-Carotene in Mice Inoculated With C3HBA Adenocarcinoma Cells: Lack of Therapeutic Action of Supplemental Ascorbic Acid[1,2,3,4]

Giuseppe Rettura, *Ph.D.,*[5] **Francis Stratford,** *M.D.,*[5] **Stanley M. Levenson,** *M.D.,*[5] *and* **Eli Seifter,** *Ph.D.*[5,6]

ABSTRACT—Decreased tumor incidence, increased latent period, and increased survival time were observed in C3H/HeJ mice fed supplemental β-carotene for 3 days and then inoculated with 10^4 C3HBA (syngeneic) tumor cells. In addition, C3H/HeJ, C3H/He, and CBA/J mice, fed supplemental β-carotene beginning immediately after they were inoculated with 2×10^5 C3HBA tumor cells, showed decreased tumor growth and increased survival time. When β-carotene was fed to mice in which palpable tumors were already present, it similarly slowed tumor growth and extended animal survival time. Ascorbic acid supplementation (5 g/kg diet), introduced into the experiment as a possible synergist for β-carotene's antitumor action, was without therapeutic action when tested in the presence or absence of β-carotene supplements. The basal diet, a standard commercial mouse chow, contains more vitamin A than the National Research Council's recommended dietary allowance for normal rodents and supports normal growth, reproduction, and longevity of normal mice. The work reported here is the first demonstration of the antitumor action of β-carotene in animals with a transplanted tumor.—JNCI 1982; 69:73–77.

Previous work from our laboratory showed that supplemental vitamin A in nontoxic amounts has both tumor preventive and therapeutic actions in C3H and CBA mice inoculated with C3HBA adenocarcinoma cells (*1*, *2*). Additionally, we showed that supplemental vitamin A has similar prophylactic and therapeutic action in two other animal tumor model systems—MuSV and BW10232 (*3*, *4*). Because dietary carotenes are the usual source of vitamin A for herbivores and omnivores such as mice, and because we have shown recently that supplemental β-carotene has marked tumor preventive and therapeutic actions in mice inoculated with an oncogenic virus (M-MuSV), we tested the action of β-carotene in a nonviral transplantable tumor system that responds to vitamin A.

MATERIALS AND METHODS

Animals.—Inbred female C3H/HeJ and male CBA/J mice were obtained at 5 weeks of age from The Jackson Laboratory, Bar Harbor, Maine. Female C3H/He mice of similar age were obtained from the Charles River Breeding Laboratories, Wilmington, Mass. The animals were examined, weighed, and allocated randomly to cages housing 5 mice/cage in a room with a 12-hour day–night cycle, at a temperature of 25°C and relative humidity of about 35%. C3H mice were used in experiments 1, 2, and 5, and CBA mice were used in experiments 3 and 4.

Diets.—In experiments 1 and 2 the mice were maintained on a powdered laboratory chow (Teklad, Inc., Monmouth, Ill.) which served as the basal or control ration. It contains 6,190 IU vitamin A palmitate/kg diet and 4.3 mg β-carotene (equivalent to 7,167 IU vitamin A); the total 13,357-IU/kg diet is well above the National Research Council's recommended dietary allowance of vitamin A, which averages 6,000 IU/kg diet for normal growth, pregnancy, lactation, and longevity of normal rodents. The basal control diet is, therefore, not deficient in vitamin A.

We prepared two experimental diets from the basal diet. One was made by addition of an alcoholic solution of vitamin A palmitate (150,000 IU/kg diet); the other was made by the addition of an alcoholic solution of 90 mg β-carotene/kg diet.

In experiments 3 and 4, in place of Teklad as the control or basal chow, Purina Laboratory Chow (#5001) was used (Ralston Purina Co., St. Louis, Mo.). It contains considerably more vitamin A (15,000 IU/kg) than the Teklad product; in addition, it contains 6.5 mg β-carotene/kg diet.

Tumors.—Adenocarcinoma C3HBA (*5*) was obtained from The Jackson Laboratory as a transplant in young C3H/HeJ female mice. The inocula were prepared from solid tumors 1.2 cm in diameter. The tumor tissue was gently minced in a cold phosphate-buffered saline solution containing penicillin and streptomycin and filtered through a wire screen. The residue was discarded, and the filtrate was centrifuged for 10 minutes at 1,800×*g*. The supernatant was discarded and the precipitate was suspended in cold buffer. To count the viable cells, we stained an aliquot of the suspension with 0.4% trypan blue. The concentration of cells was adjusted with buffer so that a 0.1-ml suspension contained 1×10^6 viable cells. Mice received tumor cells sc in

an area of the nipple line, approximately 1.3 cm above the right inguinal lymph node.

In experiments 1 and 2, female C3H/HeJ mice were used; in experiments 3 and 4, male CBA/J mice were used as recipients. Inocula for these experiments were prepared by passing the C3HBA tumor through CBA hosts, harvesting the tumors, and then preparing the inocula as described above. In experiment 5, we used C3H/He female mice from the Charles River Breeding Laboratories. Inoculation was sc in the outer surface of the thigh.

In all cases inoculum sites were gently palpated daily to determine the date of tumor appearance. After a tumor appeared, its size was estimated daily with the use of a caliper with millimeter divisions. Tumor size was recorded as the average of the major and minor diameters of the generally ovate tumor. Latency was recorded as the number of days required for the development of a palpable tumor. The latent period is a measure of tumor resistance; i.e., the longer the latent period, the more resistant the animal.

Statistical analysis.—We evaluated tumor incidence (frequency) by the chi-square method, tumor size and latent period by Student's *t*-test, and survival time by ANOVA. F-ratios were determined and where warranted, the data were further examined by the Newman-Keuls test to establish the allowable comparisons and the *P*-values for these comparisons.

Experimental design.—Experiment 1 was conducted in the spring of 1979, and its purpose was to study the effect of β-carotene on tumor incidence. For this reason, we used an inoculum size that did not produce tumors in all animals; thus we could detect if a treatment increased or decreased tumor incidence. Earlier we found that the TD_{50} for C3H/HeJ mice was approximately 10^4 cells (*6, 7*) and that some treatments could alter the tumor incidence when inoculated with TD_{50} for controls (*8*). Groups of 10 C3H/HeJ female mice each were fed one of the diets. Group I received the basal or control ration (Teklad). Group II mice received the vitamin A-supplemented diet, and group III mice received the β-carotene-supplemented diet. On the 4th day all mice were inoculated sc with 10^4 C3HBA tumor cells in the nipple line above the right inguinal lymph node.

Experiment 2 was conducted in the spring of 1978. Three groups of 10 C3H/HeJ female mice were established and maintained on the basal chow for 1 week. The mice were then inoculated with 2×10^5 C3HBA tumor cells as described for experiment 1. We used this inoculum ($2\times TD_{100}$) to ensure 100% tumor incidence (*8*); in this way we could study the influence of β-carotene on tumor latent period. Directly after inoculation, mice were fed one of the three Teklad-derived diets as described above.

Experiments 3 and 4 were started in November and December 1980, respectively. In experiment 3, 3 groups of 10 CBA/J male mice maintained on the Purina basal chow were inoculated in the outer aspect of the thigh with 2×10^5 C3HBA tumor cells. When the tumor sizes reached mean diameters of 6.2 mm 13 days later, 1 group of mice was continued on the basal chow, a second group was switched to the vitamin A-supplemented diet, and the third group was switched to the β-carotene-supplemented diet. Groups of mice without tumors were established in experiment 3; because they received the same amounts of vitamin A and β-carotene as did those with tumors, observations could be made on the toxicity of vitamin A and β-carotene over a long time period (*9*).

Experiment 5 was performed in the spring of 1981. Its purpose was to examine the possible effect of a single level of AA supplementation on C3HBA tumor growth and to uncover a possible AA-carotene interaction. Four groups of 10 female C3H/He mice, maintained on Purina Laboratory Chow, were inoculated with 2×10^5 C3HBA tumor cells. When tumor size reached 7.5 mm, the mice were treated with experimental diets as follows: 1 group was continued on the control ration, a second group received the control ration supplemented with β-carotene (90 mg/kg diet), a third group received the control ration supplemented with AA, (5 g/kg diet), and a fourth group received both β-carotene and AA supplements in the amounts described.

RESULTS

Growth and possible vitamin A toxicity.—In experiment 3, mice without tumors have been maintained on vitamin A- and β-carotene supplemented chow for 13 months. During the experimental period, the mice were weighed several times. All groups gained 14 g and the average weight at 13 months was 35±1.3 g. After the animals had been on the diets for 9 months, they were all subjected to diagnostic X-ray to determine if pathologic bone fractures were present.

TABLE 1.—*Effect of supplemental vitamin A and β-carotene on tumor incidence, latent period, and survival time in C3H/HeJ female mice inoculated with 1×10^4 C3HBA tumor cells (Expt 1)*

Group	Diet supplement	Tumor incidence[a]	Latent period, days[b]	Tumor size, mm[c]		Survival time, days[b,c]
				Day 32	Day 46	
I	None	6/10	21.7±3.2	5.0±0.4	13.5±0.5	70.2±4.0

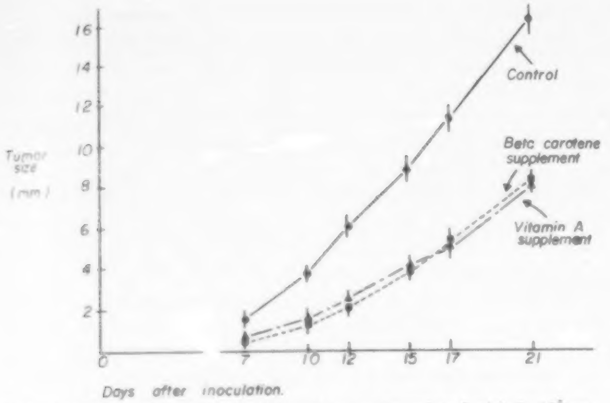
[a] No. of mice with tumor/no. of mice inoculated. Data were analyzed by the chi-square method.

[b] Values are means ± SE. Latent period and tumor size were analyzed by Student's *t*-test; survival time was analyzed by the ANOVA.

[c] Of the tumor-bearing animals.

[d] NS = not significant ($P>0.05$); NA = not allowable comparison. Mean is absent.

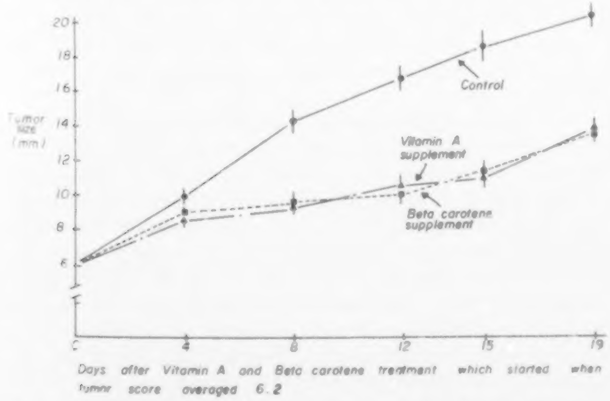


TEXT-FIGURE 1.—Female C3H/HeJ mice were inoculated with 2×10^5 syngeneic C3HBA cells. Feeding of supplemented diets was started several hours after inoculation.

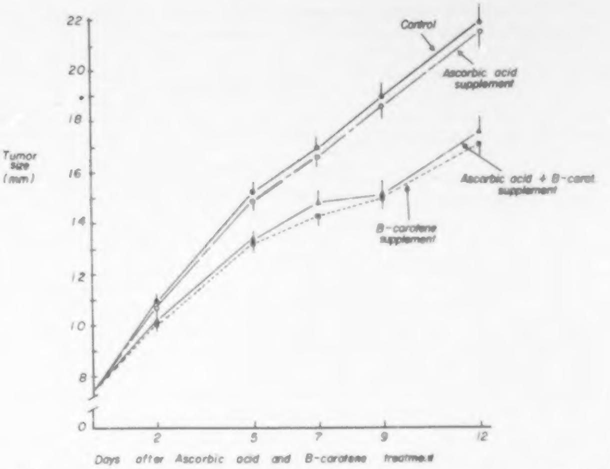
We found no fractures and did not observe difficulty or pain in walking in any animal. Exfoliative or other dermatitis or dermatosis were not noted. Other signs of possible vitamin A toxicity have not, as yet, been explored.

Tumor incidence.—In experiment 1, the only experiment in which we began supplemental β-carotene feeding before tumor inoculation, each supplement decreased tumor incidence in mice inoculated with 1×10^4 tumor cells. There was no statistically significant difference between the effects of vitamin A ($P<0.02$) and β-carotene ($P<0.05$; table 1). All mice in experiments 2–5 developed tumors; thus neither vitamin A nor β-carotene influenced tumor incidence when 2×10^5 tumor cells were inoculated (expt 2).

Latent period.—The latent period for mice inoculated with 1×10^4 tumor cells was 21.7±3.2 days (expt 1), and 6.1±0.4 days for those receiving 2×10^5 cells (expt 2), $P<0.001$. The effect of vitamin A on the latent period for mice receiving 1×10^4 tumor cells could not be determined due to the diminished tumor incidence. Although β-carotene increased the latent period in the same experiment, the differences were not statistically significant. β-Carotene and vitamin A each increased the latent period significantly when the inoculum size was 2×10^5 cells (8.8±0.6 days for β-carotene, 8.9±0.5 for vitamin A vs. 6.1±0.4 for controls; $P<0.001$ for each treatment).



TEXT-FIGURE 2.—Male CBA/J mice were inoculated with 2×10^5 C3HBA tumor cells. Treatments were begun when tumor diameters were 6.2± 0.3 mm (mean ± SE; range=5.5–7.0 mm).



TEXT-FIGURE 3.—Female C3H/He mice were inoculated with 2×10^5 C3HBA tumor cells. Treatments were started when tumor diameters were 7.5±0.2 mm (mean ± SE; range=7.0–8.0 mm).

Tumor growth.—Supplemental β-carotene and vitamin A each slowed tumor growth in all experiments, but neither treatment caused tumor regression. Supplemental ascorbic acid by itself did not influence tumor growth rate, and it did not change the effect of β-carotene supplement. (*See* text-figs. 1–3.)

Survival time.—In all cases, supplemental β-carotene and vitamin A increased survival time significantly (tables 1, 2). This was true for experiments in which the vitamin A supplements were started after tumors were already present (expts 3 and 4) as well as for those in which vitamin A was fed before inoculation (expt 1) or beginning immediately after inoculation (expt 2). Supplemental β-carotene increased survival times to the same degree as did supplemental vitamin A. AA did not increase survival times of control (basal diet) or β-carotene-supplemented tumor-bearing mice.

DISCUSSION

In the present study, C3HBA (The Jackson Laboratory) tumor growth patterns and animal survival times were similar to those in syngeneic C3H/HeJ mice, closely related C3H/He mice, and allogeneic CBA/J mice. The patterns are similar to those we observed earlier in C3H/HeJ mice (*5, 8*). In each experiment supplemental vitamin A or β-carotene showed antitumor activity as measured by increased survival times. In each experiment vitamin A supplementation decreased tumor growth and prolonged survival to a degree previously reported for mice with C3HBA tumors (*10, 11*). The effects of supplemental β-carotene on tumor growth inhibition and increase in survival time were similar to those due to vitamin A.[7] Supplemental AA by

[a] In experiment 2, vitamin A and β-carotene supplements were started immediately after tumor inoculation; in experiment 3, when tumor score averaged 6.2±0.3 mm; in experiment 4, when tumor score averaged 5.7±0.2 mm; and in experiment 5, vitamin A, β-carotene, and AA supplements were begun when tumor score averaged 7.5±0.2.

[b] Values are means ± SE; survival time was analyzed by the ANOVA.

[c] —=comparison could not be made.

itself did not influence tumor growth or animal survival, and it did not modify the antitumor action of supplemental β-carotene.

The basis of the anti-C3HBA tumor action of supplemental vitamin A has not been established. We have suggested that vitamin A influences host responses that limit tumor growth; at the dose we have used, vitamin A is not cytotoxic. We showed that this level of supplemental vitamin A stimulates immune responses in mice. The responses include *a*) lymphopoiesis (*12, 13*), thymopoiesis (*14, 15*), enhancement of allograft skin rejection (*16, 17*), and enhancement of antiviral host reactions directed against M-MuSV (*3*) or pox virus (*18*). It is a significant finding that supplemental vitamin A can stimulate these immune-related phenomena in animals that show depressed immune function due to tumor disease (*16*), chemical toxicity, or physical injury (*19*). Although differences in the effects of supplemental vitamin A and β-carotene on C3HBA tumor growth are not evident in our experiments, the data do not permit us to determine if the actions of β-carotene reported in this paper require that it be converted to vitamin A; the experiments were not designed to adduce this specific point. Supplemental β-carotene was as active as supplemental vitamin A in inhibiting tumor growth, which suggests either that 1) β-carotene need not be converted to vitamin A for this activity or that 2) the mouse is able to convert a sufficient portion of the β-carotene supplement to obtain a vitamin A-like antitumor response. This phenomenon has been discussed elsewhere (*19, 20*). Similarly, we have discussed the significance of the longer time required for dietary β-carotene to become liver vitamin A for tumor prevention and therapy (*19*).

In previous studies we used some graded doses of vitamin A (*21*) and found that a 150,000-IU/kg diet gives reproducible results and, in the time intervals we use, no discernible toxicity. Earlier in this discussion, we suggested that the antitumor action of vitamin A is not dependent on cytotoxicity against either the tumor or the host; i.e., vitamin A was not present under conditions that caused a decrease in tumor size or weight loss of the host. Vitamin A, in doses that cause lysosomal labilization, may be used under conditions (>350,000 IU/kg diet) that cause tumor regression; however, in our experience, these doses also cause weight loss and toxicity.

We considered the possibility that the C3HBA tumor-preventive action of β-carotene and vitamin A observed in experiments 1 and 2 is related to the effects of these compounds or that of their metabolites on maintenance of epithelial differentiation. If this were so, *all-trans*-retinoic acid (which promotes epithelial differentiation) would inhibit C3HBA tumorigenesis as it does in 7,12-dimethylbenz[*a*]anthracene tumorigenesis (*22*). However, we found that levels of retinoic acid that do not influence weight changes (10 mg/kg diet) do not alter C3HBA tumor incidence at the TD_{50}; larger amounts of retinoic acid cause both weight depression and increased tumor frequency and growth rate. Vitamin A protects against this toxicity of retinoic acid, which shows that retinoic acid toxicity is not vitamin A toxicity.

The results suggest that there are at least two mechanisms involved in the antitumor action of vitamin A and, therefore, in that of β-carotene. One of these mechanisms involves the role of vitamin A in the promotion of epithelial differentiation. This role can be fulfilled by chemicals lacking other vitamin A activity, such as reproduction or sense perception. However, the other role of vitamin A (and of β-carotene) in tumor prevention and therapy involves lymphopoiesis and immune mechanisms. This requirement, in our experience, is not fulfilled by compounds that are not convertible to retinol in vivo. Although retinoic acid may stimulate an in vitro killer cell activity against tumor cells (*23*), the relevance of this action to the inhibition of tumor growth in vivo is highly questionable.

We examined the influence of supplemental AA in this system because of the current interest in a possible antitumor action of AA in C3H mice (*24*) and because we have considered a possible role for AA in the metabolism of β-carotene. AA was postulated by us (*20*) to be a cofactor for the dioxygenase enzyme that converts β-carotene to vitamin A (*25*). If this theory is correct, under some conditions dietary AA could promote the conversion of β-carotene to vitamin A. If the antitumor action of β-carotene were dependent on its conversion to vitamin A, dietary AA might contribute to the antitumor action of β-carotene. In the present experiments the inactivity of AA does not exclude the possibility that under certain conditions it has a tumor chemotherapeutic action, particularly in animals that require AA, such as guinea pigs or in mice that were fed an inhibitor of AA biosynthesis, e.g., lycorine.

Flow Cytometric Analysis of R3327 Rat Prostate Adenocarcinoma Grown In Vivo and In Vitro[1,2,3]

Alice J. Claflin,[4] **Alan Pollack,**[4,5] **Theodore Malinin,**[4] **Norman L. Block,**[5,6] *and* **George L. Irvin**[4,5,7]

ABSTRACT—The Dunning R3327 transplantable prostate adenocarcinoma in the Copenhagen rat is an acceptable model for the human disease. The G-subline (a rapidly growing carcinoma) and the H-subline (a slow-growing, well-differentiated adenocarcinoma) represent the extremes of differentiation and growth rate of this tumor. Both sublines were found to have one population that was diploid and a second aneuploid population that was hyperdiploid in DNA content. The percentage of hyperdiploid cells was significantly higher in R3327-G tumors than in R3327-H tumors. The tumor cell population ratios were stable in vivo, but the in vitro culture conditions supported only cells with diploid DNA content following four to five subcultures. These predominantly diploid cultured cells, when injected into intact male rats, resulted in tumors that had both diploid and aneuploid cells.—JNCI 1982; 69:79–87.

The utilization of animal models of human disease often permits a more precise investigation than is possible with human subjects. The Dunning R3327 transplantable prostate adenocarcinoma is an acceptable model for this disease, with the same diversity as that of the disease in humans in relation to growth rate, cellular variation, differentiation, and response to a variety of therapeutic modalities (*1–4*). The tumor subline designated R3327-G is a rapidly growing, poorly differentiated, androgen-dependent carcinoma. The R3327-H tumor subline grows slowly and is well differentiated and androgen-dependent.

We have previously shown that the response of the poorly differentiated R3327-G subline to endocrine manipulation is reflected in population shifts as identified by FCM (*5–7*). The ratio of the number of hyperdiploid cells to the total number of cells (diploid + hyperdiploid) was used successfully to predict response to therapy. The proportion of hyperdiploid cells was chosen because in R3327-G tumors there appeared to be two proliferating cell types, of which one population was aneuploid (3.2C in G_0+G_1 phase). The possibility that two distinct cell populations with potentially different rates of proliferation coexist in a transplantable tumor prompted the following investigation.

In this communication we established that both R3327-G and R3327-H tumors contained two proliferating cell populations. Each subline consisted of one cell population with normal rat DNA content per cell (diploid) and 42 chromosomes, whereas the other was near-tetraploid and aneuploid in DNA content (hyperdiploid in G_0+G_1 phase). Thus the ratio of hyperdiploid to the total cell population (percent hyperdiploid) by FCM reflects the proportion of aneuploid cells in the tumors. The percentage of hyperdiploid cells was found to be significantly higher in R3327-G tumors than in R3327-H tumors. To investigate the mechanisms of in vivo coexistence and stability of two proliferating tumor subpopulations (diploid and aneuploid), we used cell culture techniques. We observed that aneuploid cell proliferation was limited in vitro. The following report is a systematic investigation of these in vitro changes by FCM.

MATERIALS AND METHODS

Cell culture.—Solid tumors (R3327-G and R3327-H), grown in male COP × F344 rats, were enzymatically dispersed to single cells as previously described (*2*). The tissue was minced and placed in trypsinization flasks with enzyme solution consisting of 0.25% trypsin, 0.02% EDTA, and 1,300 U collagenase/ml in PBS; the mixture was stirred at room temperature and the supernatant decanted at 20-minute intervals. Enzyme activity was reduced by the addition of cold CMRL-1415 medium (GIBCO, Grand Island, N.Y.) containing 10% calf serum. The cells were washed once, resuspended, and counted, and viability was determined by trypan blue exclusion. Approximately 10^6 dispersed tumor cells were seeded into 75-cm^2 plastic tissue culture flasks. Medium consisted of CMRL-1415 containing 2.0 mg $NaHCO_3$/ml, 100 U penicillin/ml, 100 µg streptomycin/ml, and 10% (vol/vol) newborn bovine serum. The flasks were gassed with 10% CO_2 in air to adjust the pH, caps were tightened, and the flasks were placed in a 37°C incubator. The medium was changed 1 day later and thereafter twice a week. The cells were subcultured at confluence (5–7 days) by treatment with 0.25% trypsin and 0.02% EDTA in PBS. The detached cells were washed and counted, and the flasks were reseeded with approximately 10^5 cells. The cultured

tumor cells were harvested by enzyme treatment and washed, and viability was determined. Cultured cells were injected sc with 10^7 viable cells per injection site.

Preparation of cells for karyotype determination.—The trypsin-dispersed tumor cells at their first subculture were seeded into 75-cm^2 plastic tissue culture flasks at a concentration of 1.5×10^5/ml (3×10^6/flask). After 24 hours in culture, 0.5 ml of 0.5 µg/ml vinblastine sulfate (Velban; Eli Lilly & Co., Indianapolis, Ind.) was added to each flask. The cells were incubated overnight in the presence of vinblastine sulfate and harvested by trypsinization. The cells were washed and suspended slowly in 5 ml of hypotonic solution (1 part fetal bovine serum:6.5 parts distilled water). The cells were incubated at 37°C for 17 minutes, and four to five drops of fixative (1 part glacial acetic acid:3 parts methanol) were added. The cells were washed once in freshly prepared fixative, and the slides were prepared. The cells were stained with Gurr Giemsa (Searle Diagnostics, High Wycombe, Bucks, England). Ten cells from the G-tumor and 12 cells from the H-tumor were analyzed.

FCM.—Solid tumor tissue or aliquots of 10^6 cells from each subculture were monitored by FCM for changes in ploidy. Small pieces of solid tumor tissue were frozen in teasing buffer [0.1 *M* Trizma Base, 5 ml/liter 37% HCl, and 0.08 *M* NaCl (pH 7.4)] as described previously (*5-8*). The tissue was thawed, teased in 0.5 ml of teasing buffer, and filtered through 60-µm nylon mesh. The suspension was diluted in 3.5 ml of staining solution (0.01 *M* Trizma Base, 700 U RNase 1-A/liter, 0.1% Nonidet P40, 10 m*M* NaCl, and 7.5×10^{-5} *M* propidium iodide). The concentrations of fluorescent nuclei were quantitated with the use of a hemacytometer in a fluorescence microscope. The nuclei were further diluted to a concentration of $1-2\times10^5$/ml and stored overnight at 4°C before they were run on the flow cytometer (TPS-1; Coulter Electronics Inc.). Since propidium iodide fluorescence is proportional to double-stranded nucleic acid (*9*) and measurements were made on isolated nuclei in the presence of RNase, the resulting fluorescence was proportional to DNA content. All DNA histograms were obtained with the use of a TPS-1 flow cytometer (Coulter Electronics Inc.). Those DNA histograms that were analyzed were smoothed, and the 2C peak was translocated to channel 25 (*10*). We obtained the percentage of hyperdiploid cells by summing the number of particles between 20 and 95 and multiplying the sum by 100 (*5, 7, 8*).

Two types of standards were used in the FCM. Rat spleen was prepared in the same manner as the tumor cells for use as an external 2C standard. At the beginning of each series of samples run on the cytometer, the spleen standard was positioned on channel 25. Periodically, between tumor samples, the rat spleen standard was analyzed to ensure that no fluctuation had occurred. Also, mixing experiments were performed, whereby the rat spleen standard was mixed with the tumor sample to further confirm the position of the diploid cells. In some of the samples, an internal fluorescent microsphere standard was included (1/8 brights; Coulter Electronics Inc.). These fluorescent microspheres were included to monitor changes in the coefficient of variation that might occur as a consequence of instrumentation (e.g., partial clogs) or staining problems.

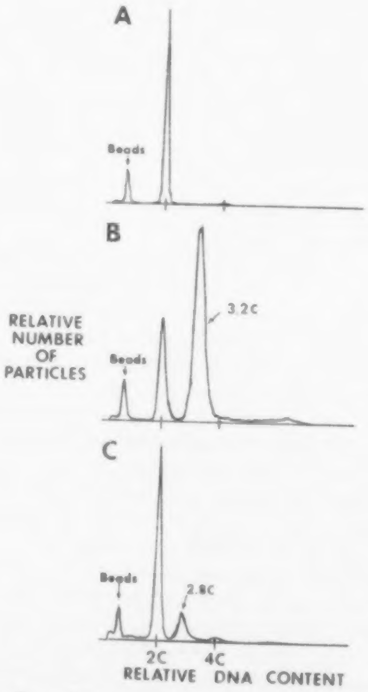
RESULTS

Histology

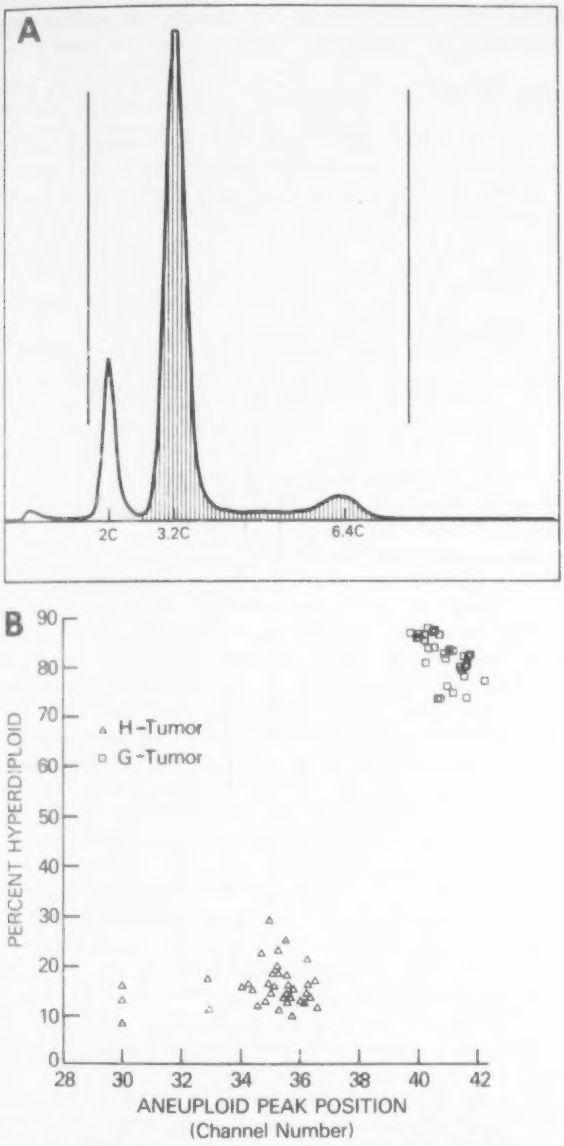
Histologic examination of the tumor resulting from R3327-H cultured cells demonstrated a well-differentiated adenocarcinoma consisting of irregularly arranged glandular structures composed of multilayered uniformly appearing epithelial cells (fig. 1). Histologic examination of the tumor resulting from R3327-G cultured cells demonstrated a tumor composed of densely packed primitive cells in disarray and numerous blood vessels throughout (fig. 2). Histologically, the tumors resulting from cultured cells were not different from the tumor of origin.

FCM of R3327-H and R3327-G Tumors In Vivo

FCM of R3327-H and R3327-G tumors showed that both contained major hyperdiploid (greater than 2C) peaks characteristic of aneuploid G_0+G_1 cells (text-fig. 1). The hyperdiploid peak was at 3.2C for R3327-G tumors and 2.8C for R3327-H tumors. Along with this difference in peak position, there were more hyperdiploid cells in poorly differentiated R3327-G tumors than in well-differentiated R3327-



Text-figure 1.—Representative flow cytometric DNA histograms of normal rat spleen cells (A), R3327-G rat prostate adenocarcinoma cells (B), and R3327-H cells (C). *Ordinate* represents relative number of particles, and the *abscissa* represents relative fluorescence intensity. Since the fluorochrome used was propidium iodide, fluorescence intensity is proportional to relative DNA content. The smaller peaks *to the left* (marked *beads*) are from 1/8 bright fluorescent microspheres (Coulter Electronics Inc.) that were added as an internal standard. The labels 2C and 4C mark the positions where diploid and tetraploid cells would be located, respectively. The R3327-G tumor (B) was harvested at day 50, and the R3327-H tumor (C) was harvested at day 100.

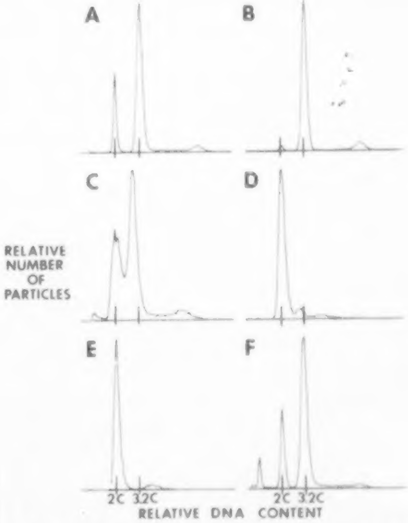


TEXT-FIGURE 2.—Flow cytometric comparison of R3327-H tumor and R3327-G tumor grown in intact male rats for 3-6 mo and 1-2.5 mo, respectively. Multiple pieces from 10 R3327-H tumors and 25 R3327-G tumors were analyzed. Each histogram was smoothed, the diploid peak translocated to channel 25 (*2*), the percentage of hyperdiploid cells calculated, and the aneuploid peak position determined. Panel A illustrates the areas used for the percent hyperdiploid calculation [the number of cells in the *shaded area* was divided by the number of cells between the *vertical lines* (*5, 7*)]. The results are displayed in panel B. In those histograms in which the computer could not find an aneuploid peak, the aneuploid peak position was said to be located at channel 30. R3327-G tumors had an average of 81.6%±4.7 (1 SD) hyperdiploid cells, and R3327-H tumors had an average of 16.4%±4.3 ($P<0.001$).

H tumors. These differences are shown quantitatively in text-figure 2. The two tumor sublines were found to be significantly different from each other ($P<0.001$) both in terms of the proportion of hyperdiploid cells and the position of the aneuploid G_0+G_1 peak. R3327-G tumors had an average of 81.6% hyperdiploid cells as compared to 16.4% for R3327-H tumors. We have shown previously that in R3327-G tumors the proportion of hyperdiploid cells remains relatively constant throughout the life of the tumor (*8*). Multiple biopsies of both tumor sublines showed that the R3327-G tumor has less variability than the R3327-H. When R3327-H tumors were left in vivo for 3-4 months, they frequently became multilobed, consisting of higher proportions of aneuploid cells in some sections as opposed to others. In some sections, detectable numbers of aneuploid R3327-H cells were lacking altogether.

FCM of R3327-G and R3327-H Tumor Cells In Vitro

The proliferation of enzyme-dispersed R3327-G and R3327-H tumor cells was further studied in cell culture by FCM. Text-figure 3B shows that when R3327-G cells were first subcultured (following 5 days of cell culture), the aneuploid population predominated. Although there were more aneuploid cells present at the first subculture, the proportion of proliferating aneuploid cells could not be determined by FCM alone. In fact, there were very few cells in aneuploid S-phase (approximately 3.4C to 6.2C). In subsequent passages the proportion of diploid cells increased such that by the fourth to fifth subculture (text-fig. 3E) no aneuploid cells were detectable by FCM. This decrease in the proportion of aneuploid cells to undetectable levels occurred in the absence of any change in ploidy. The aneuploid G_0+G_1 was located at approximately 3.2C, even when the proportion of aneuploid was less than 25% (text-fig. 3D). Chromosome analysis of vinblastine sulfate-blocked R3327-G cells in passages 4-5 in cell culture confirmed the



TEXT-FIGURE 3.—FCM of R3327-G tumor cells in vitro. Solid tumor tissue (A). Tumor cells at the time of first subculture at day 5 (B), second subculture (C), third subculture (D), and fifth subculture (E). Solid tissue from tumor that resulted from injected culture cells at the fifth subculture (F). *Small peak to the left of the 2C position in panel F* is from 1/8 bright fluorescent microspheres (Coulter Electronics Inc.) that were used as an internal standard.

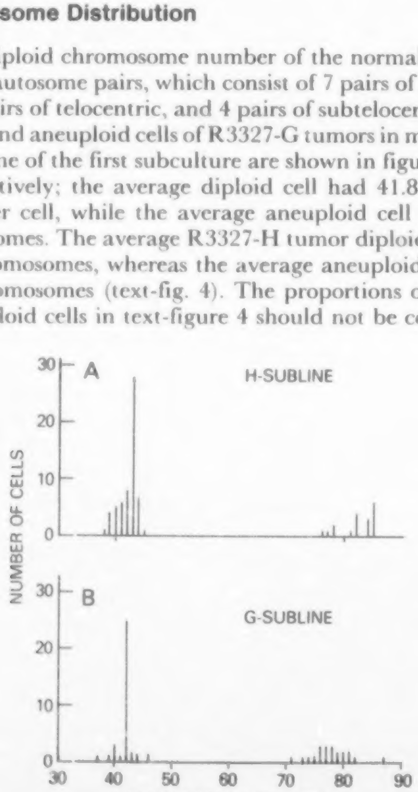
FCM in that no aneuploid cells were found. The average chromosome number of these cells was always close to the normal somatic cell average of 42. The karyotype of these predominantly diploid cultured cells was similar to that of the diploid cultured cells at the first subculture.

The addition of 1–5 μg testosterone (Sigma Chemical Co., St. Louis, Mo.) in the culture media had no significant effect on the loss of the aneuploid population in vitro. The sc injection of these predominantly diploid cells into male rats gave rise to tumors that were palpable in the same amount of time as tumor cells that had not been cultured in vitro. Also, the tumors resulting from predominantly diploid cultured cells contained a large proportion of aneuploid cells, typical of tumors originating from an in vivo transfer (text-fig. 3F). These data suggest that *a*) diploid cells may give rise to aneuploid cells or *b*) aneuploid cells were present in vitro in small, undetectable numbers. In either case, the proportion of aneuploid cells returned to its usually high level (80–90%) and stabilized. This stability in the ratio of diploid to aneuploid tumor cells in vivo has been demonstrated previously (*8*).

Enzyme-dispersed R3327-H cells behaved like R3327-G cells in vitro. The aneuploid population in this case was lost more rapidly (one to two subcultures) and returned when predominantly diploid cells from the fourth to the fifth passage in vitro were implanted sc in intact male rats.

Chromosome Distribution

The diploid chromosome number of the normal rat is 42 with 20 autosome pairs, which consist of 7 pairs of metacentric, 9 pairs of telocentric, and 4 pairs of subtelocentric. The diploid and aneuploid cells of R3327-G tumors in metaphase at the time of the first subculture are shown in figures 3 and 4, respectively; the average diploid cell had 41.8 chromosomes per cell, while the average aneuploid cell had 77.9 chromosomes. The average R3327-H tumor diploid cell had 42.4 chromosomes, whereas the average aneuploid cell had 82.2 chromosomes (text-fig. 4). The proportions of diploid to aneuploid cells in text-figure 4 should not be compared, since a higher number of diploid spreads was acceptable for counting.



TEXT-FIGURE 4.—Distribution of the number of chromosomes per cell in R3327-G and R3327-H tumors.

DISCUSSION

The relationship between altered chromosomes and the change of normal cells to cancer cells remains an enigma. In human prostate carcinoma it has been observed that increasing anaplasia parallels the increasing occurrence of hyperdiploid cells (*11*, *12*). Our tumor model parallels the human disease in that anaplastic R3327-G has 80% hyperdiploid cells. Conversely, the well-differentiated H-subline has many fewer hyperdiploid cells.

We have shown that under the in vitro culture conditions selected for the growth of the diploid populations in the G- and H-sublines of the R-3327 rat prostate adenocarcinoma, the aneuploid cells appeared to proliferate only during the first 5 days of cell culture. Subsequent passages in vitro eventually resulted in a loss of detectable numbers of aneuploid cells. Thus the aneuploid cells appeared to have a limited proliferative capacity in vitro.

This disparity between in vivo and in vitro cell growth has been reported by others (*13*, *14*). Cells with increased DNA content do not appear to arise de novo under the condition described, and the apparent stability of the diploid cell in vitro reported here is striking. Implantation of these predominantly diploid cells sc into male rats resulted in tumors containing both diploid and aneuploid cells. The tumor growth rate and the ratio of diploid to aneuploid cells were the same as those for tumors from in vivo transplanted tumor cells. The selection of diploid tumor cells in vitro was, therefore, completely reversed by implantation in vivo. These data suggest that some factor(s) were missing in vitro which were *a*) necessary for the extended proliferation of aneuploid cells or *b*) necessary for the transition of diploid cells into aneuploid cells. In the former case, aneuploid cell proliferation would be reduced to undetectable levels in vitro. In the latter case, the proliferative capacity (number of cell divisions) of the aneuploid population is assumed to be limited in vivo or in vitro and the rate at which the transition from diploid to aneuploid occurred would determine the ratio of diploid to aneuploid.

It is doubtful that testosterone is solely responsible for sustaining aneuploid cell proliferation in vivo, since testosterone had little effect on aneuploid cell proliferation in vitro. We have recently reported that although a reduction in serum androgen levels affected an increase in the ratio of diploid to aneuploid cells, the proportion of aneuploid cells was reduced but not eliminated (*5*, *8*). Some other environmental factor(s) appear necessary to sustain aneuploid proliferation in vitro. In light of the results reported here, the constancy in the ratio of diploid to aneuploid tumor cells in vivo probably depends on several environmental conditions. Should these conditions be identified and characterized, our ability to limit aneuploid cell proliferation might be greatly enhanced.

Depression of Natural Antitumor Resistance of C57BL/6 Mice by Leukemogenic Doses of Radiation and Restoration of Resistance by Transfer of Bone Marrow or Spleen Cells From Normal, But Not Beige, Syngeneic Mice[1,2]

E. Gorelik[3,4] *and* **R. B. Herberman**[3,5]

ABSTRACT—Small fractionated doses of radiation (4 weekly doses of 179 rad) induced leukemia in 93% of C57BL/6J mice. These leukemogenic doses of radiation were associated with suppression of natural killer (NK) cell activity, as assessed in vitro by cytotoxic activity of spleen cells or in vivo by the ability of irradiated mice to eliminate iv inoculated radiolabeled YAC-1 lymphoma cells. This suppressive effect of irradiation was profound and prolonged, being detectable for at least 7 weeks after the last dose of radiation. NK reactivity of irradiated C57BL/6 +/+ or C57BL/6 beige mice could be reconstituted by iv transfer of 10×10^6 bone marrow cells or 50×10^6 spleen cells from normal C57BL/6 mice. In contrast, transfer of bone marrow or spleen cells from beige donors did not change the NK reactivity of irradiated C57BL/6 +/+ or C57BL/6 *bg/bg* recipients. It was also shown that the irradiation protocol did not eliminate potentially reactive NK cells, because following interferon incubation (10^3 U/ml), the NK activity of spleen cells of irradiated mice was substantially increased. This study supports the hypothesis of an important role for NK cells in radiation-induced leukemogenesis and forms the basis for exploration of the needed, more direct data on the effects of reconstitution of NK activity on subsequent development of tumors.—JNCI 1982; 69:89–93.

The concept of natural antitumor resistance predicts that NK cells and other natural effector cells play an important role in the elimination of malignant cells and can be considered as the first line of defense in immune surveillance (*1, 2*).

Despite the attractiveness of this hypothesis, actual documentation of the participation of natural cell-mediated immunity in the prevention of primary spontaneous or induced carcinogenesis has been difficult. Experimental support for this concept would come from data showing that carcinogenic factors suppress NK reactivity and, further, that selective restoration of this reactivity in carcinogen-treated animals would interfere with carcinogenesis.

There already are a few pieces of evidence in this direction. Certain carcinogenic factors (irradiation, 7,12-dimethylbenz[*a*]anthracene, and urethan), in addition to their ability to suppress specific humoral and/or T-cell-mediated immunity, have also been shown to strongly suppress natural cell-mediated immunity (*3–5*).

The investigations on the suppressive effects of irradiation of NK cells have been performed mainly with single, relatively high (lethal or sublethal) doses of radiation. NK activity has usually been found to be relatively radioresistant, with little or no effect immediately or at 1 day after treatment (*3, 6*). However, by 2 weeks after sublethal irradiation, NK activity of spleen cells dramatically declined (*3*). Transfer of normal bone marrow cells not only may protect mice from the lethal effects of irradiation but also may reconstitute their NK activity. The degree of reconstitution of NK reactivity has been found to depend on the genotype of the bone marrow donors, with high NK activity transferred only by bone marrow cells obtained from high NK-reactive strains of mice (*7*).

Bone marrow cells of C57BL/6J beige mice, which have a selective deficiency in NK reactivity, have been able to reconstitute several immunologic functions in lethally irradiated mice but failed to reconstitute the NK activity in the recipients (*8*). The doses of radiation and schedules of irradiation used in most of the above investigations are lethal. It is still unclear whether a carcinogenic schedule of irradiation can be suppressive for the natural cell-mediated immunity.

Small fractionated doses of radiation (160–170 rad, 4 weekly doses) have been shown to be particularly effective in inducing a high incidence of thymic lymphomas (*9, 10*). It was found that transfer of normal bone marrow or spleen cells into mice treated with such a leukemogenic schedule of irradiation could strongly inhibit the development of tumors (*9, 10*), but the mechanism of this protection is unclear.

In the present study, we analyzed the depression of NK reactivity of C57BL/6 mice by a leukemogenic schedule (179 rad, 4 weekly doses) of irradiation and examined the ability of transplanted syngeneic bone marrow or spleen cells to reconstitute their NK activity. This experimental model was particularly attractive because it allowed a comparison of the effects of transferred bone marrow or spleen cells from normal C57BL/6 mice with those of transferred bone marrow or spleen cells from C57BL/6 beige mice. Reconstitution of NK activity by cells from normal C57BL/6 mice and not from beige mice would provide strong evidence for a direct radiation-induced impairment in NK cells or their stem cells rather than for the presence of a

suppressive environment that inhibits the expression of NK cells. Furthermore, such findings should indicate the usefulness of this model for assessment of the role of NK cells in prevention of radiation-induced leukemogenesis.

MATERIALS AND METHODS

Mice.—C57BL/6J +/+ and C57BL/6J *bg/bg* mice were obtained from The Jackson Laboratory, Bar Harbor, Maine, at 3.5 weeks of age.

Tumor cells.—YAC-1, a tissue culture cell line of a Moloney virus-induced lymphoma of A/Sn origin, was used as target cells. This culture cell line was maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum, 2 m*M* glutamine, 25 m*M* HEPES,[6] 50 μg gentamicin, and 100 μg penicillin and streptomycin (hereafter referred to as "complete medium").

Irradiation.—Whole-body irradiation was performed with the use of a cesium-137 source of irradiation. Gammacell 40, manufactured by Atomic Energy of Canada Limited, Ottawa, Canada, was used as the irradiation unit. The irradiation was started when the mice were 28±3 days old. Whole-body radiation at a dose of 179 rad (138 rad/min) was applied four times at weekly intervals.

Bone marrow or spleen cell reconstitution.—One or 2 days after the last dose of radiation, the mice were given iv 10×10^6 bone marrow cells or 50×10^6 spleen cells from nonirradiated 2- to 3-month-old C57BL/6 +/+ or C57BL/6 beige mouse donors.

CRA.—At different times after the last dose of radiation, 3–4 mice from every experimental group were killed, and spleen cell suspensions were prepared (*5*). YAC-1 cells, at 1×10^7 in 1 ml of RPMI-1640 medium, were incubated for 1 hour at 37°C with 200 μCi of $Na^{51}CrO_4$ (sp act, 1 mCi/mmol; Radiochemical Centre, Amersham, Buckinghamshire, England).

In some experiments tumor cells were labeled with ^{111}InOx according to the method of Wiltrout et al. (*11*). The relatively low level of spontaneous release of radioactivity from the ^{111}InOx-labeled tumor cells permitted the use of these cells in long-term cytotoxicity assays. YAC-1 cells, 10^7/ml, were incubated with 10 μCi ^{111}InOx for 10 minutes at room temperature in complete medium. After three washes, tumor cells were resuspended at 1×10^5/ml. Cytotoxic activity of the spleen cells was analyzed in a microcytotoxicity assay.

^{51}Cr-labeled tumor cells (5×10^3) were incubated with various concentrations of effector cells (ranging from 200:1 to 23:1 E:T ratios) in quadruplicate in microtiter plates (Linbro Scientific Inc., Hamden, Conn.) for 4 hours at 37°C. ^{111}InOx-labeled cells (5×10^3) were incubated with spleen cells for 16 hours. The supernatants were collected with the use of a Skatron Titertek rapid-harvesting system (Flow Laboratories, Inc., Rockville, Md.). The percent cytotoxicity was calculated (*5*). The differences between the means were consistently found to be significant ($P<0.05$) when Δm_1-m_2 was more than 2 SD (or 4 SE) of m_1 or m_2.

IFN boosting of NK reactivity of spleen cells of the recipients.—Spleen cells (10^7) were obtained from mice at 4 weeks after the last dose of radiation and were incubated for 16 hours at 37°C with murine IFN (10^3 U/ml) in complete medium. Partially purified IFN (4.4×10^7 U/mg protein) was obtained from the late Dr. K. Paucker, the Medical College of Pennsylvania, Philadelphia, Pa. After incubation, cells were washed twice and tested in a 4-hour CRA against YAC-1 target cells.

In vivo cytotoxicity assay.—In vivo natural antitumor resistance was assessed by a modification of the method previously described (*12*). We found that the kinetics of clearance from the lungs of [^{125}I]deoxyuridine- and ^{51}Cr-labeled YAC-1 cells was identical, and in the present study ^{51}Cr-labeled YAC-1 cells (1×10^6/0.5 ml) were inoculated iv into the tail veins of mice at various times after the last dose of radiation. The level of radioactivity remaining in the lungs at 3 hours after tumor cell inoculation was measured in a gamma scintillation counter.

RESULTS

Irradiation with 179 rad weekly four times induced thymic lymphomas in 93% of irradiated C57BL/6 mice. The results presented in table 1 indicated that this irradiation schedule substantially depressed the NK activity of spleen cells. Even 4 weeks following the last dose of radiation, the cytotoxic activity of spleen cells was still depressed. After iv inoculation of 10×10^6 bone marrow cells of C57BL/6 +/+ mice into irradiated mice, the NK activity of spleen cells was significantly increased, although it did not reach the levels observed in nonirradiated C57BL/6 mice (table 1). Transfer of bone marrow cells from beige mice had little, if any, effect on the NK activity of spleen cells against YAC-1 cells. This evaluation of the effect of irradiation on NK activity of spleen cells had some limitations, since this activity is age-dependent. Spleen cells of mice develop cytotoxic activity at 3–4 weeks of age, their activity reaches a peak at 6–8 weeks, and then it declines to low levels (*1*). In our experiments, mice were irradiated between 4 and 8 weeks of age, and when NK activity was to be assessed 2–4 weeks later, the mice were already 10–12 weeks old. This probably explains the relatively low cytotoxicity by spleen cells of untreated C57BL/6 mice, which is slightly increased in the 16-hour cytotoxicity assay. Nevertheless, in all experiments performed, the pattern shown in table 1 was reproducible (e.g., *see* data in subsequent tables). One week following transfer of bone marrow cells from C57BL/6 +/+ mice, no reconstitution of splenic NK activity was seen (data not shown). Only after 2 weeks did the NK activity of these mice significantly increase.

To assess more precisely in vivo the NK reactivity of irradiated mice, we analyzed their ability to eliminate iv inoculated radiolabeled YAC-1 cells from the lungs. Elimination of radiolabeled YAC-1 cells from the lungs was significantly depressed in irradiated mice, with almost three times more cells remaining at 3 hours than in the lungs of nonirradiated control mice (table 1). After transfer of bone marrow cells from C57BL/6 +/+ mice, the ability to eliminate tumor cells from the lungs was considerably higher than it was in irradiated mice and was similar to that in

[a] Mice were irradiated (179 rad) weekly for 4 wk. One day following the last dose (at 7 wk of age), mice were inoculated iv with 10×10^6 of bone marrow (BM) cells from normal C57BL/6 or beige mice. Four weeks later (at 11 wk of age) the cytotoxic activity of their spleen cells was tested in a 16-hr assay against ^{111}InOx-labeled YAC-1 cells, and clearance of radiolabeled tumor cells from the lungs was also evaluated.

[b] 0.5×10^6 ^{51}Cr-labeled YAC-1 cells were inoculated iv, and the level of radioactivity remaining in the lungs was determined 3 hr later. The number of radiolabeled YAC-1 cells in the lungs at 10 min following inoculation was the same in all groups of mice tested.

normal control C57BL/6 mice (table 1). In contrast, bone marrow cells from beige donors failed to restore the antitumor resistance of irradiated C57BL/6 mice. In the next series of experiments, beige mice also were irradiated and transplanted with bone marrow cells (table 2). In comparison with normal C57BL/6 mice, nonirradiated beige mice had a lower ability to destroy YAC-1 cells in vitro or in vivo. However, as previously reported (*13*), beige mice were not completely deficient in natural cytototoxic function, since after irradiation (179 rad four times) their ability to eliminate tumor cells after iv inoculation was further diminished (table 2). Also, by comparison of the natural antitumor resistance of irradiated C57BL/6 +/+ and C57BL/6 *bg/bg* mice, it appears that the schedule of irradiation did not suppress completely the antitumor activity in C57BL/6 +/+ mice, because their reactivity was still significantly greater than that of irradiated C57BL/6 beige mice (table 2).

Transfer of bone marrow cells of C57BL/6 +/+ mice into irradiated beige mice reconstituted the cytotoxic reactivity of these mice to levels above those of nonirradiated beige mice and close to, but not identical with, those in nonirradiated C57BL/6 +/+ mice. In contrast, transfer of bone marrow cells from beige donors did not significantly change the NK reactivity of irradiated C57BL/6 +/+ or C57BL/6 *bg/bg* recipients.

The weight of the thymus in irradiated mice was lower than that in nonirradiated mice (table 2). In irradiated and reconstituted mice the weight of the thymus was even higher than that in nonirradiated C57BL/6 +/+ or C57BL/6 *bg/bg* mice. Bone marrow of normal C57BL/6 +/+ and C57BL/6 *bg/bg* mice was equally efficient in the reconstitution of thymus weight in irradiated mice (table 2).

Transfer of spleen cells (50×10^6) gave results quite similar to those produced by bone marrow cells. Spleen cells from C57BL/6 +/+ mice, but not from C57BL/6 *bg/bg* mice, were efficient in the reconstitution of natural antitumor resistance of irradiated C57BL/6 +/+ or C57BL/6 *bg/bg* mice (table 3).

Thus our data indicate that small fractionated doses of radiation, a schedule that has been repeatedly shown to be strongly leukemogenic for C57BL/6 mice, substantially inhibit the natural cytotoxic reactivity of these mice. Even at 7 weeks following irradiation, the natural antitumor resistance of irradiated C57BL/6 +/+ or beige mice did not return to the levels of nonirradiated mice (table 3).

Although fractionated doses of radiation (179 rad four times) inhibited spontaneous NK reactivity, the treated mice still had IFN-responsive pre-NK cells. After 16 hours of incubation of their spleen cells with IFN (10^3 U/ml), NK activity dramatically increased (table 4). However, the levels of reactivity of spleen cells from irradiated mice did not reach those of IFN-treated spleen cells from nonirradiated

or reconstituted mice. Transfer of 10×10^6 bone marrow cells from beige C57BL/6 mice into irradiated mice was unable to restore the spontaneous NK activity of spleen cells, but this procedure did efficiently reconstitute IFN-augmentable activity (table 4).

DISCUSSION

The first investigations of the effect of irradiation on the NK cell activity indicated that NK cell function is relatively radioresistant (*3, 6*). However, strong and prolonged suppression of NK activity of spleen cells was observed 2 weeks after irradiation (*3*). This decrease of NK reactivity was paralleled by the appearance of suppressor cells (*3*).

In the present study we analyzed the influence of small fractionated doses of radiation, a schedule that is strongly leukemogenic in C57BL/6 mice, on the NK reactivity of irradiated mice. Our data indicated that this schedule of irradiation (179 rad four times) very efficiently suppressed NK activity. This suppressive effect was profound and persisted for at least 7 weeks after the last dose of radiation. Such investigations on the duration of the suppressive effect of irradiation (or other factors) on the in vitro NK activity of spleen cells are complicated by the age dependence of NK activity. NK activity of spleen cells of mice older than 10 weeks gradually decreases and might come to the level observed in the treated mice. Parkinson et al. (*14*) reported depressed NK activity of spleen cells of mice treated with small split doses of radiation. However, the differences between irradiated and control mice tended to be small due to the problems discussed above of age-dependent decline of NK activity. We have found that the ability of mice to eliminate iv inoculated YAC-1 lymphoma cells is less age-dependent. At least at 12–14 weeks of age, when the spleen cells of normal C57BL/6 mice had low levels of NK activity, the mice were as efficient in the elimination of tumor cells from the lungs as were younger mice. Therefore, the analysis of the clearance of iv inoculated tumor cells may be a more useful method for assessment of the natural antitumor resistance of mice undergoing various treatments over a period of several weeks. NK reactivity of irradiated mice can be reconstituted. It was previously shown that NK activity could be restored by administration of normal C57BL/6 bone marrow cells to lethally irradiated mice (*8*). In contrast, bone marrow cells of beige mice failed to restore NK reactivity of lethally irradiated mice, although such treatment did restore other immunologic functions in these mice (*8*). Similarly, in our experiments bone marrow or spleen cells of normal C57BL/6 mice were able to reconstitute NK reactivity of C57BL/6 +/+ or C57BL/6 *bg/bg* mice irradiated with fractionated doses of sublethal radiation (179 rad four times), and bone marrow or spleen cells from beige donors were inefficient in the restoration of NK cell function. Also, transfer of bone marrow or spleen cells from C57BL/6 +/+ mice into fractionally irradiated beige mice resulted in a substantial increase in NK reactivity. These data support the hypothesis that the low levels of NK activity of beige mice are due to an intrinsic defect in the NK cells (*8*). In addition, the ability of bone marrow or spleen cells from normal C57BL/6 mice to reconstitute the NK activity of sublethally irradiated mice is consistent with the hypothesis that this treatment protocol does not induce an inhibitory or suppressive environment, but rather that the irradiation induces some deficit in pre-NK cells and/or their stem cells. Alternatively, the finding that spleen cells from irradiated mice can display quite substantial levels of NK activity after IFN treatment suggests that the radiation may induce a deficit in positive in vivo regulation of NK activity rather than in the NK cells themselves.

The split doses of radiation (179 rad four times) that we have shown to be strongly suppressive for NK cell activity of C57BL/6 mice have also been demonstrated to be strongly leukemogenic, with 93% of irradiated C57BL/6 mice developing thymomas by 6 months after irradiation. Transplantation of bone marrow or spleen cells into such irradiated mice by a protocol very similar to that shown here to reconstitute NK activity has been shown to inhibit the irradiation-induced leukemogenesis (*9, 10*). Thus these data are consistent with the hypothesis that NK cells play an important role in antileukemia defense. It will be of interest to examine the effects on natural antitumor resistance of the same schedule of irradiation in older C57BL/6 mice or in mice of other strains, which are relatively resistant to the leukemogenic effects of such treatments. Further experiments are needed also to define more precisely the mechanism of radiation-induced depression of NK activity and particularly to assess more directly the role of NK cells in resistance to radiation-induced leukemogenesis. Studies are now in progress to determine the incidence of radiation-induced lymphoma in beige mice and to determine the ability of bone marrow or spleen cells from beige mice to restore resistance to radiation-induced leukemogenesis.

Spontaneous Occurrence of Atypical Hyperplasia and Adenocarcinoma of the Uterus in Androgen-Sterilized SD Rats[1,2]

Shinichi Morikawa,[3] Souei Sekiya,[3] Masabumi Naitoh,[3] Hiroshi Iwasawa,[3] Bin Takeda,[3] *and* **Hiroyoshi Takamizawa[3]**

ABSTRACT—In SD female rats sterilized by a single injection of testosterone propionate at 2 days after birth, the spontaneous occurrence of atypical hyperplasia and adenocarcinoma of the uterus was observed for a fairly long period (>2 yr). Two atypical hyperplasias and 2 adenocarcinomas were detected in 25 androgen-sterilized rats (ASR) after 500 days of age; in contrast, in 111 normal control rats no abnormal uterine proliferation was detected during a 750-day observation period. These results indicate that a persistence of both hormone imbalances and dysfunctional uteri in ASR induces abnormal uterine proliferation at a late age.—JNCI 1982; 69:95–101.

Anovulatory sterility is considered one of the major high-risk factors of endometrial hyperplasia and adenocarcinoma in humans (*1*). Although hormone imbalance characteristic of anovulatory sterility appears to be the cause of endometrial carcinogenesis (*2*), direct evidence for this explanation has not yet been obtained.

The rate of spontaneously occurring endometrial hyperplasia and adenocarcinoma is extremely low in both mice and rats as compared to the rate in old rabbits, in which such abnormal uterine proliferations are of relatively high incidence (*3, 4*). The highly varied patterns of endometrial hormone conditioning seen among these species seem to support this finding (*5*). In Sprague-Dawley rats, uterine tumors were detected in only 25 (0.9%) of 2,723 female rats at 600–800 days of age (*6–10*). Neither was atypical hyperplasia or adenocarcinoma of the uterus noted in these reports. We therefore set up an animal model of anovulatory sterility in Sprague-Dawley rats, and for the fairly long period of more than 2 years, we compared the spontaneous occurrence of uterine tumors in ASR with that in NR.

MATERIALS AND METHODS

Pregnant SD rats were purchased from a commercial breeder (Clea Japan, Inc., Tokyo). More than 200 newborn rats were used. They were housed in plastic cages in an air-conditioned (25±2°C), artificially illuminated room and were separated from their mothers after 3 weeks of age. Weaned rats were given commercial rations (Oriental M; Oriental Yeast Co., Ltd., Tokyo, Japan) and tap water ad libitum.

A single sc injection of 1.25 mg T propionate (Teikoku Hormone Manufacturing Co., Ltd., Kanagawa, Japan)/0.05 ml of sesame oil was given by the method of Barraclough (*11*) to each of 100 2-day-old female rats. Fertility of the ASR and an equal number of NR was checked at 70 days by the mating of 1 male:3 females for 30 days. Vaginal smears by the Papanicolaou staining method were examined daily for 2 weeks before autopsy.

After blood was collected from the portal veins of lightly ether-anesthetized rats, serial autopsies were performed on 70- to 750-day-old ASR and NR. Wet weights of the uteri, ovaries, adrenal glands, and pituitary glands were determined immediately after excision. These organs were then fixed in 10% neutral Formalin, sectioned serially, stained with hematoxylin and eosin, and examined by optical microscopy.

Plasma was obtained by centrifugation of the blood at 3,000 rpm for 15 minutes and was stored at −20°C until it was assayed. The plasma values of gonad steroids such as E_1, E_2, P, and T were estimated with CEA-IRE-SORIN radioimmunoassay kits (Japan Radioisotope Association, Tokyo). Effect of ovariectomy and E_2 on the uterus weight and peroxidase induction was examined in 70-day-old NR and ASR. Both NR and ASR were ovariectomized at 50 days of age and given a single injection of 40 μg E_2 (Sigma Chemical Co.)/kg body weight on the 18th day after ovariectomy. The animals were killed 48 hours after E_2 administration, and the uterus weights and peroxidase activities were measured, as described below. The cytosol E_2 receptor of the uterus was assayed according to the dextran-coated charcoal assay method of McGuire and DeLaGarza (*12*), as described previously (*13*). As described in a previous report (*14*), uterine peroxidase activity was assayed by the method of Himmelhoch et al. (*15*) with guaiacol as substrate. Protein was measured by the method of Lowry et al. (*16*).

RESULTS

Hormone Imbalance in ASR

In the ASR, vaginal opening was observed in only 63% of the animals, even after 300 days of age, whereas it was observed in all NR at about 45 days of age. The infertility rate of the ASR was 98%, and all ASR showed both a lack of sexual cyclicity and a persistence of estrus, as determined by vaginal smear after 70 days of age.

As shown in table 1, the body weights of the ASR were significantly greater than the body weights of the NR, and

TABLE 1.—*Mean body and organ weights ± SE of NR and ASR with age*

Treatment group	Age, days	No. of rats	Body weight, g	Organ weight, mg			
				Uterus	Ovary	Adrenal glands	Pituitary gland
NR	100	9	267±12	641±60	78±3	99±4	25±2
ASR	100	11	267±5	473±20[a]	92±10	113±9	25±3
NR	300	10	311±8	806±38	140±10	93±4	28±1
ASR	300	11	393±17[b]	520±45[b]	91±6[b]	98±4	25±2
NR	550	11	332±19	845±66	179±19	157±18	28±4
ASR	550	22	406±10[b]	611±40[c]	114±14[d]	120±6	32±3

[a] $P<0.02$.
[b] $P<0.001$ as compared to the values of NR.
[c] $P<0.01$ as compared to the values of NR.
[d] $P<0.05$ as compared to the values of NR.

obesity became prominent in the ASR with aging. In contrast to the body weights, although the organ weights of the uterus and ovary of the ASR increased with age, the significance of the increase was less than the significance of the increase in body weights.

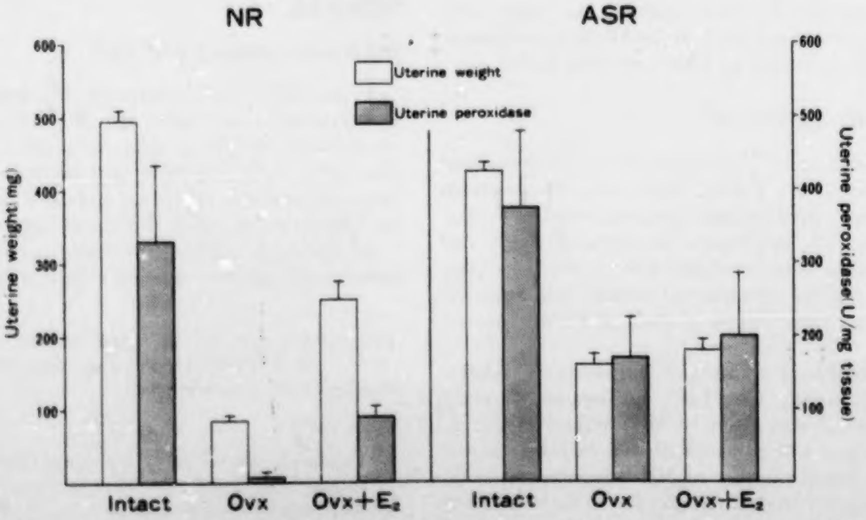
As shown in text-figure 1, the response of uterus weight to ovariectomy in ASR was less as compared to the response in NR, and exogenous E_2 administration to ovariectomized ASR as young as 70 days old failed to exert any tropic action on the uterus weight. A similar phenomenon was also evident for uterine peroxidase induction by E_2 administration. However, no significant difference in the mean cytosol E_2 receptor content of the uteri of 5 rats was observed when ASR (138 fmol E_2/mg protein) were compared to NR (128 fmol E_2/mg protein).

As shown in text-figure 2, the plasma P values for ASR at both 300 and 750 days of age were significantly lower than the values for NR. This finding seems related to the absence of corpora lutea in the ovaries of the ASR. However, the values for the other gonad steroids E_1, E_2, and T were not significantly different between ASR and NR. Therefore, the plasma (E_1 + E_2):P ratio was increased in the ASR.

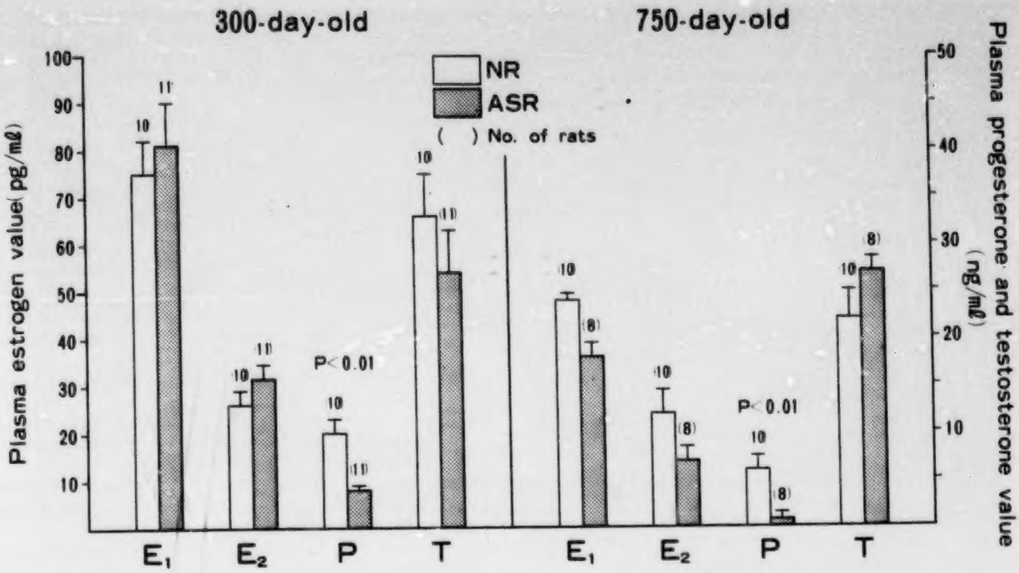
Spontaneous Occurrence of Atypical Hyperplasia and Adenocarcinoma of the Uterus in ASR

As shown in table 2, abnormal uterine proliferation was not detected in any of the 111 NR during a 750-day observation period. In contrast, 2 atypical hyperplasias were detected in 500-day-old (fig. 1) and 570-day-old ASR, respectively, and 2 adenocarcinomas of the uterus were detected in 25 ASR after 500 days of age. Both uterine carcinomas were characterized by cytologic atypia, such as enlarged nuclei and prominent nucleoli, as well as by histologic atypia, such as back-to-back arrangement of glands and mesenchymal destruction. One of the uterine adenocarcinomas was detected at 500 days of age and was histologically diagnosed as an adenocarcinoma composed of both differentiated (fig. 2) and poorly differentiated (fig. 3) types. The other uterine adenocarcinoma was detected at 730 days of age and was composed of an undifferentiated type of adenocarcinoma (fig. 4), a differentiated type of squamous cell carcinoma (fig. 5), and a squamous type of metaplasia. Metastasis was not found in either of these carcinomas.

Other tumors of nonuterine origin, such as mammary,



TEXT-FIGURE 1.—Effect of ovariectomy (Ovx) and E_2 administration on the uterus weight and peroxidase induction in 70-day-old NR and ASR. *Bars* represent means ± SE for 5 rats.



TEXT-FIGURE 2.—Plasma gonad steroid levels in 300- and 750-day-old NR and ASR.

adrenal, or pituitary tumors, were detected in 11 (33%) of 33 NR and in 4 (16%) of 25 ASR after 500 days of age. These results suggest that the spontaneous occurrence of endocrine-related tumors except those of the uterus was suppressed in ASR as compared to NR. Whereas squamous-type metaplasia of the uterine epithelium was detected in 25 (36%) of 70 ASR during a 750-day observation period and it increased with aging, no squamous metaplasia was observed in any of the 111 NR.

TABLE 2.—*Spontaneously occurring atypical hyperplasia and adenocarcinoma of the uterus in NR and ASR*

Treatment group	Age, days	No. of rats	Uterine tumors		Other tumors
			Atypical hyperplasia	Adenocarcinoma	
NR	70–499	78	0	0	0
NR	500–750	33	0	0	11[a]
ASR	70–499	45	0	0	0
ASR	500–750	25	2	2	4[b]

[a] Of the 11 tumors, 6 were of the mammary gland, 3 were of the adrenal gland, and 2 were of the pituitary gland.

[b] Of the 4 tumors, 2 were of the mammary gland and 2 were of the pituitary gland.

DISCUSSION

The effects of neonatal androgenization on the proliferation of rat uterine epithelium have been described by several investigators (*11, 17–19*). Tall columnar luminal epithelium, its squamous-type metaplasia, and pyometra (data not shown) are characteristic in ASR during a relatively short observation period of within 1 year. Such morphologic changes of the uterine epithelium in ASR are considered to be due to a continuous estrogen effect unopposed by P, inasmuch as the changes are similar to those produced by the administration of high doses of estrogens for prolonged periods (*17, 20, 21*). However, atypical hyperplasia and adenocarcinoma of the uterus so far have not been induced in rats by only excess estrogenic stimulation (*22, 23*), whereas their induction has been reported in rabbits (*24, 25*).

Spontaneously occurring uterine adenocarcinoma in hormonally imbalanced (persistent estrus) rats, i.e., without the use of any carcinogens including estrogens, has been reported only by Pfeiffer (*26*) who detected a uterine adenocarcinoma in an aged, 816-day-old female rat in which testes had been implanted at birth. However, hormone imbalance was not fully elucidated in his report.

The present study also provides direct evidence that atypical hyperplasia and adenocarcinoma of the uterus can occur spontaneously with fairly high incidences in aged ASR as compared to similarly aged NR. The cause of such abnormal uterine proliferations in ASR is not precisely known, but it is possibly a result of the complex hormone imbalances in ASR, such as lack of sexual cyclicity (persistent estrus) (*11, 27, 28*), decreased responsibility of the uterus particularly to exogenous estrogen (*27, 29–31*), and an increased endogenous E_2:P ratio (*29*), as observed in the present experiments. Among these causes, the E_2:P ratio seems to be important, because E_2:P in ASR with adenocarcinoma was about twice that in ASR without adenocarcinoma.

Such hormone imbalance of ASR occurring as early as 70 days of age precedes the occurrence of abnormal uterine proliferations, which are usually detected after 500 days of age. Thus the uterine carcinogenesis in ASR appears to require a fairly long time from the onset of both hormone imbalance and a dysfunctional uterus. Although a continuous estrogenic stimulation unopposed by P is needed in endometrial carcinogenesis, the present results obtained with androgenized rats suggest that a dysfunctional uterus of long duration is fundamental to endometrial carcinogenesis.

Combined Inhibitors of Carcinogenesis: Effect on Azoxymethane-Induced Intestinal Cancer in Rats[1,2,3]

Norman D. Nigro,[4] **Arthur W. Bull,**[4] **Paulette S. Wilson,**[4] **Barbara K. Soullier,**[4] *and* **Majid A. Alousi**[5,6]

ABSTRACT—Outbred male Sprague-Dawley CD rats were fed a complete semisynthetic diet and were given supplemental low doses (2 ppm) of selenium as H_2SeO_3 in their drinking water or 50 mg 13-*cis*-retinoic acid (13-*cis*-RA) and 2 g β-sitosterol/kg diet either singly, in combinations of two, or in combinations of all three. Intestinal tumors were induced with eight weekly sc injections of 8 mg azoxymethane (AOM)/kg body weight, and inhibition of tumor formation was determined by tumor counts after 26 weeks. Noncarcinogen controls for each dietary group received eight injections of sterile water. Tumor inhibition was statistically significant in 2 groups of animals: Dietary control animals had a tumor frequency of 5.07 tumors/rat, rats receiving selenium- plus 13-*cis*-RA supplementation had a tumor frequency of 3.77, and those being given the combination of all three inhibitors had 2.75 tumors/rat. Analysis of fecal steroids from 3 AOM groups (dietary controls, the β-sitosterol plus 13-*cis*-RA-supplemented group, and the group receiving all three additives) after 4 months of supplementation showed that the addition of β-sitosterol to the diet had no effect on acidic or neutral steroids, regardless of the observed difference in tumor frequency. These results suggest that subpharmacologic doses of inhibitors, particularly those that inhibit the process by different mechanisms, while ineffective alone, may provide significant inhibition of tumorigenesis when used in combination.—JNCI 1982; 69:103–107.

There is considerable evidence from epidemiologic and laboratory studies indicating that the etiology of cancer of the large intestine in humans is due to predominantly dietary factors. The dietary elements most suspect are a combination of excessive amounts of animal fat and relatively little fiber (*1*). Studies suggest that alterations of fat and fiber in the diet needed to reduce cancer incidence would have to be substantial. In fact, such profound dietary changes are not likely to be acceptable to the population in general (*2*).

However, prevention may be accomplished by other dietary measures. For example, cancer could be prevented best by eliminating or by effectively modifying the metabolism of the carcinogen. The difficulty with this approach is that the carcinogen responsible for intestinal cancer in humans is unknown, and it is extremely difficult to identify (*3*). In addition, known modifiers of initiation are few, and the time in which they act is short. However, we have more information about the inhibition of promotion. As a consequence, the use of inhibitors of the promotional phase appears to offer the best opportunity for reducing the high incidence of cancer of the large intestine (*4*).

Several chemicals have been shown to inhibit cancer formation in various organs in animals. These include selenium, the retinoids, and the plant steroids. Selenium has been shown by Jacobs (*5*) and Soullier et al. (*6*) to be an effective inhibitor of colon cancer in rats. The retinoids, especially 13-*cis*-RA, have been shown to inhibit cancer formation in the bladder, skin, breast, and lung (*7*). There is only limited evidence that 13-*cis*-RA inhibits intestinal cancer formation (*8*). Raicht et al. (*9*) have shown that β-sitosterol has some inhibitory effect on intestinal carcinogenesis in animals.

While the mode of action of these inhibitors is unknown, they appear to affect the process differently. There is precedent for suspecting that when small amounts of several inhibitors are used together they may enhance the total inhibitory effect significantly. The object of this experiment is to investigate that possibility.

MATERIALS AND METHODS

AOM was obtained from Ash-Stevens, Inc., Detroit, Mich., and was prepared as an aqueous solution for injection. Dextrose was purchased from a bakery supply house. Beef fat was donated by the Belmont Packing Co., Detroit, Mich., and was rendered in the laboratory. The 13-*cis*-RA was a gift from W. E. Scott, Hoffmann-La Roche Inc., Nutley, N.J. The β-sitosterol (95%) was donated by E. R. Diller, Eli Lilly & Co., Indianapolis, Ind. Other dietary components were obtained from Bioserve, Inc., Frenchtown, N.J. The same lot of each dietary component was used throughout the experiment. Selenium as H_2SeO_3 (99%) was purchased from the Ventron Corp., Alfa Products Division, Danvers, Mass.; it was prepared as a 1-g/liter stock solution, neutralized with NaOH, and added to double-distilled deionized water to a final concentration of 2 mg H_2SeO_3/liter. All other chemicals were obtained from sources previously described (*10*).

Outbred male Sprague-Dawley CD rats that weighed 100–125 g (6 wk old) were purchased from Charles River Breeding Laboratories, Wilmington, Mass. Animals were caged individually, diets and water were given ad libitum, body weights and water consumptions were recorded weekly, and food consumptions were determined every 4

ABBREVIATIONS USED: AOM=azoxymethane; 13-*cis*-RA=13-*cis*-retinoic acid.

TABLE 1.—*Basic diet: Composition*

Component	Weight, %	Total calories, %
Protein[a]	20.000	20.97
DL-Methionine	0.200	
Salt mix[b]	3.600	
Vitamin mix[c]	2.000	
Beef fat	5.000	11.80
Dextrose	45.155	47.31
Corn starch	19.000	19.92
Cellulose	5.000	
Placebo beadlets[d]	0.045	

[a] Vitamin-free casein (#11319; Bioserve, Inc.).

[b] Bernhart-Tomarelli salt mix, modified (#1468; Bioserve, Inc.) containing 735.0 g calcium phosphate, 81.0 g dipotassium phosphate, 68 g potassium sulfate, 30.6 g sodium chloride, 21.0 g calcium carbonate, 21.4 g disodium phosphate, 25.0 g magnesium oxide, 11.64 g ferric citrate, 810 mg zinc carbonate, 4.212 g manganese carbonate, 333 mg cupric carbonate, 7.2 mg potassium iodide, and 997.8 mg citric acid/kg salt mix.

[c] Vitamin mix (#1468; Bioserve, Inc.) containing 0.8 g vitamin A plamitate (250,000 U/g), 0.20 g vitamin D_2 (500,000 U/g), 15.4 g α-tocopherol (250 U/g), 100 g choline bitartrate, 0.05 g menadione, 4.5 g niacin, 0.5 g riboflavin, 0.7 g pyridoxine HCl, 0.1875 g thiamin HCl, 1.2 g calcium pantothenate, 0.03 g biotin, 0.2 g folic acid, 1.25 g vitamin B_{12}, and 874.9825 g sucrose/kg mixture.

[d] Stabilized gelatin beadlets.

weeks. Feces were collected over a 72-hour period during the 16th week of the experiment, their weights were recorded, and samples were frozen for subsequent neutral and acid steroid analysis. At least 15 animals in each dietary group were used for fecal collections, and samples from 2 animals were pooled.

The animals were divided into groups according to carcinogen administration and dietary supplementation. There were 8 groups of 30 rats given the carcinogen AOM (8 mg/kg body wt for 8 wk) and 8 groups (noncarcinogen controls) of 15 rats given injections of sterile water. The basic diet as defined in table 1 was supplemented with the inhibitors listed in table 2. Each supplement was given singly or in combination of two or of all three inhibitors as follows: Selenium was given in the drinking water at 2 ppm H_2SeO_3 (1.22 ppm Se^{4+}) in double-distilled deionized water, 13-*cis*-RA was added to the food (50 mg/kg diet) in stabilized gelatin beadlets (11% 13-*cis*-RA), and β-sitosterol was added to the food at 2 g/kg diet at the expense of cellulose. The dietary control groups were given the basic diet plus placebo gelatin beadlets.

After 26 weeks all animals were killed, necropsies were performed, and all tissues were examined grossly for tumors. The number, size, and location of intestinal tumors were recorded. Tumor distributions in the small intestine as well as the proximal and distal halves of the large intestine were also tabulated. Livers from 6 animals, and 15–20 representative intestinal tumors were removed from each group. These specimens were fixed in 10% Formalin, embedded in paraffin, and stained with hematoxylin and eosin.

Bile acids and neutral steroids were extracted from fecal samples of groups A, D, and H (table 2) according to the method of Cohen et al. (*11*). Thin-layer chromatography of bile acid samples was not necessary (*12*). Major bile acids that were detected and quantitated were lithocholic, hyodeoxycholic, deoxycholic, chenodeoxycholic, 12-ketolithocholic, and cholic acids. All data were analyzed with Student's *t*-test (*13*).

RESULTS

Body Weight and Food and Water Consumption

Weight curves for animals in the various groups are presented in text-figure 1. The administration of AOM to rats resulted in significantly ($P<0.05$) reduced body weights compared to those of noncarcinogen controls on the same diet for all groups except D, F, and G. There were no other significant differences in body weights among the various dietary groups. No differences were observed in either food

TABLE 2.—*Tumor incidence and frequency*

or water consumption throughout the study. The average daily intake of the different inhibitors was 38.8 μg Se^{4+}/rat, 1.31 mg 13-*cis*-RA/rat, and 49.8 mg β-sitosterol/rat.

Tumor Frequency and Distribution

Tumor frequency and incidence in rats treated with AOM are shown in table 2. Most animals receiving the carcinogen developed intestinal tumors, and the incidence varied from 90 to 100%. When compared to the dietary controls (group A), the total number of intestinal tumors per rat was significantly reduced when 13-*cis*-RA and selenium were administered in combination (group F, $P<0.05$). The reduction was even greater when all three inhibitors were given together (group H, $P<0.0005$). The degree of inhibition varied only slightly in the different segments of the intestinal tract. Group F rats had fewer tumors in the proximal half of the large intestine as compared to the number of tumors in rats in control group A. Group H had a reduction in tumors throughout the intestinal tract. However, when β-sitosterol was given alone (group C), the average number of tumors in the small intestine was significantly increased as compared to the number of tumors in the control group A ($P<0.025$).

TABLE 3.—*Fecal neutral steroids and bile acids*[a]

Group	Neutral steroids			Total bile acids[b]
	Coprostane	Cholesterol	β-Sitosterol	
A[c]	2.0±1.5	2.2±1.4	0.2±0.7	2.9±1.1
D[d]	2.0±1.7	3.5±2.1	14.6±7.9[e]	2.7±0.7
H[f]	1.9±1.4	2.7±1.7	10.4±5.3[e]	2.4±0.1

[a] Results are expressed as mg/g feces ± SD. Only trace levels of coprostanone were detected in all groups.

[b] Total bile acids = Σ cholic + chenodeoxycholic + deoxycholic + hyodeoxycholic + lithocholic + 12-ketolithocholic acids.

[c] Controls.

[d] β-Sitosterol plus 13-*cis*-RA supplemented.

[e] $P<0.01$ when compared to control group A.

[f] All three inhibitors combined.

One hundred fifty-five tumors, which varied in size from 2 mm to 2.2 cm, were examined histologically. All but 1 were malignant. However, 62% were early lesions, i.e., cancers limited to the intestinal wall, whereas the remaining 38% penetrated the wall and involved the surrounding fat. There were no significant differences between the various groups in the degree of anaplasia, the depth of invasion, or the size of the lesions.

Metastatic disease occurred in some animals in all groups. The most common form was intraperitoneal metastases, which occurred most frequently (50%) in group C. In control group A, only 3.3% had this complication, whereas the incidence in other groups was as much as 17% (groups D and G). Liver metastases occurred most often (17%) in rats in group G: All other groups had less than 7% liver involvement, except for group H which had none. Only two lung metastases were found: one in group C and one in group H. Because two or three ear tumors were found in each group, the inhibitors had no effect on this lesion.

Fecal Bile Acids and Neutral Steroids

In the 4th month of treatment, no significant differences were observed in fecal coprosterol, cholesterol, or bile acid concentrations in AOM-treated rats as a result of being fed the control diet (group A) or receiving the supplements β-sitosterol plus 13-*cis*-RA (group D) or the three inhibitors combined (group H). β-Sitosterol was significantly increased in both groups D and H ($P<0.01$). These data are presented in table 3.

DISCUSSION

Intestinal carcinogenesis is a long, complex process with multiple steps required for the development of clinical cancer (*14*). This complexity poses enormous problems for the discovery of the mechanism of each phase of the process. For example, we have little knowledge of what initiates intestinal cancer in humans or of how initiation or promotion occurs. However, the multistep process has one important advantage: It provides many opportunities for intervention. This is possible even without a full understanding of the mechanism of carcinogenesis.

Because of its reversibility and long duration, the promotional phase of carcinogenesis offers the best opportunity for interrupting the process, thereby preventing cancer formation (*15*). Most of our knowledge of promotion comes from studies of the murine skin cancer model, but evidence exists (*16*) that the same conditions apply to cancer promotion in other organs including the intestine. Although the mechanism of promotion is unknown, a number of compounds have been shown to inhibit this phase in several forms of cancer. Some appear to have a general effect, whereas others are specific for one tissue or organ (*17*). Unfortunately, most inhibitors are fairly toxic if given in large amounts over a long time. One possible solution to this problem is the use of very small amounts of two or three compounds which together might be inhibitory without being toxic. In the present study, the use of low doses of the individual inhibitors or any combination of them was not overtly toxic.

Epidemiologists have data that suggest that selenium may have cancer-preventive properties (*18*). Animal studies show that selenium inhibits cancer in several tissues including rat intestine (*5*). Soullier et al. (*6*) found selenium to be inhibitory in our laboratory even when the animals were given a potent carcinogen and a 30% fat diet, a combination that produces a strong cancer challenge. Selenium given at 4–5 ppm is not toxic to rats in 6-month experiments. However, we believe this dose is too high for consideration in any human application. Consequently, we used a much smaller dose (1.2 ppm) in this combination study. Selenium alone at this level had no inhibitory effect.

The rationale for the use of retinoids in chemoprevention is straightforward. Epithelial tissues are known to require retinoids for development and maintenance of cellular differentiation. Since carcinogenesis is a disease characterized by lack of cell differentiation, it seems reasonable to expect that retinoids might influence the process of carcinogenesis (*7*). We selected 13-*cis*-RA for this study because of its reported inhibitory effect in several cancer systems. We also hoped to provide information to resolve the conflicting reports of its ability to inhibit experimental colon cancer in rats (*8, 19*). As with selenium, we chose a lower dose of retinoid (50 mg/kg diet) than that which had been used by other investigators and thereby attempted to minimize the potential toxicity resulting from long-term use. The retinoid alone, at this level, had no inhibitory effect. Still the combination of 13-*cis*-RA and selenium, when given as a supplement to an adequate diet, inhibited the frequency of intestinal cancer induced by AOM. In another study a combination of selenium and retinyl acetate was shown to have an additive inhibitory effect on breast cancer in rats (*20*).

The plant steroid β-sitosterol is one of the major steroids in vegetables. When given orally, it is only minimally absorbed from the gastrointestinal tract (*21*). Because the β-sitosterol may alter fecal bile acid composition, it may also influence intestinal tumorigenesis. In the present study we analyzed the fecal steroids in 3 groups: the dietary controls, the group receiving β-sitosterol plus 13-*cis*-RA, and the group receiving all three inhibitors. The intent was to compare the effect of β-sitosterol on fecal steroids in animals that showed no reduction in tumors to the effect in animals that showed a reduced tumor frequency. β-Sitosterol had no effect on acidic or neutral fecal steroids, regardless of the difference in tumor frequency. The animal model provides some evidence that this plant steroid inhibits the formation of intestinal adenoma, the initial lesion in the cancer process (*9*). In this study, however, we found no evidence of an inhibitory effect when β-sitosterol was given alone or in combination with either one of the other two chemicals. In fact, when β-sitosterol was the only supplement, the frequency of small bowel tumors as well as the incidence of peritoneal metastases increased. At present we have no explanation for these observations.

In considering the inhibitory effect of selenium, 13-*cis*-RA, and β-sitosterol on carcinogenesis when administered singly, in combinations of two, and in combinations of all three, we found that the only combination of two that had any effect was that of selenium and 13-*cis*-RA. The reduction in the average number of tumors was marginally significant. However, when all three compounds were given as a supplement to an adequate diet, the inhibitory effect on the frequency of intestinal cancers was highly significant. In those groups with reduced tumor frequency, the tumors that did develop, while fewer, were approximately the same size, had the same degree of penetration, and were similarly anaplastic as tumors that developed in animals from the groups in which tumor frequency was not reduced. This suggests to us the possibility that the inhibitory effect may be an all-or-none phenomenon that occurs during a crucial transition from an initiated cell to a frankly tumorous cell, specifically, during promotion. While these experiments do not rigorously demonstrate inhibition of promotional processes as opposed to suppression of tumor growth, the fact that all tumors were approximately the same size and had the same degree of anaplasia, even in animals from groups with reduced tumor frequency, suggests that inhibition of promotional processes is the operational phenomenon.

The result of this study adds support to the concept that the use of small amounts of several agents that inhibit cancer by different mechanisms currently offers the best opportunity for development of a chemopreventive program in humans. No doubt other dietary changes would be a necessary part of the program; however, the use of effective inhibitors may permit relatively modest dietary changes that will be acceptable. Our results are encouraging, but it is apparent that more work is needed to identify the best group of inhibitors and to optimize their combined effects in a chemoprevention program.

Generation of Long-Term T-Lymphoid Cell Lines With Specific Cytotoxic Reactivity for a Syngeneic Murine Lymphoma[1,2]

Timothy J. Eberlein, *M.D.*,[3,4] **Maury Rosenstein**, *Ph.D.*,[3] **Paul J. Spiess**, *M.S.*,[3] *and* **Steven A. Rosenberg**, *M.D., Ph.D.*[3]

ABSTRACT—The long-term in vitro growth in T-cell growth factor (TCGF) of murine cytotoxic T-lymphoid cells directed against syngeneic tumor antigens was investigated. C57BL/6 mice were immunized to syngeneic FBL-3 lymphoma by two ip injections of irradiated FBL-3 lymphoma cells. Splenocytes from these animals were injected into mice with disseminated lethal FBL-3 tumor. The injection of cyclophosphamide (Cy) plus immunized lymphocytes significantly improved survival with cure of 53% of 38 animals. In comparison, treatment with Cy alone resulted in 0 of 31 cured and treatment with Cy plus unimmunized cells resulted in 0 of 40 cured ($P<0.0005$). These in vivo immunized lymphocytes were reexposed to FBL-3 tumor in vitro for 5 days in lectin-free TCGF (LF-TCGF). Although in vivo and in vitro sensitized lymphocytes exhibited no cytotoxicity toward fresh FBL-3 tumor cells in an 18-hour ^{51}Cr release assay, expansion of appropriately sensitized cells in LF-TCGF resulted in significant lysis of fresh FBL-3 tumor cells. This significant lysis was specific and lysed syngeneic FBL-3 but not syngeneic MCA-103 fresh tumor targets. This maximal specific cytotoxicity was maintained for 2.5 months. A screening assay was developed that permitted rapid identification and isolation of low-frequency cytotoxic clones with reactivity specific for FBL-3 tumor. Several of these cloned cells were grown for almost 3 months with maintenance of high degrees of specific lysis (as much as 4,500 lytic U/10^6 cells). These cytotoxic lines and clones will be of value for the study of tumor-host immunologic interactions and perhaps for use in adoptive immunotherapy.—JNCI 1982; 69:109–116.

The use of passive immunotherapy for the treatment of malignant neoplasms has been the subject of numerous studies (*1*). This approach to therapy is dependent on obtaining lymphocytes or serum capable of eliminating tumor in vivo. In vitro assays of lymphocyte sensitization to tumor-related antigens on syngeneic tumor cells provided a useful guide to the generation of lymphoid cells of potential value in adoptive transfer (*2–21*), although exact correlation between in vitro and in vivo effects was not always observed.

The in vitro generation of lymphoid cells cytotoxic for syngeneic tumor cells proved to be difficult, and in most systems only weak cytotoxic responses were seen (*22, 23*). Attempts to enhance the in vitro generation of cytotoxic effector cells emphasized the importance of macrophage presentation of tumor antigen (*4, 6, 10, 24, 25*), the use of peritoneal exudate cells (*13, 26–28*), effector cells from in vivo immunized animals (*7–10, 12–15, 17, 27, 29*) or tumor-bearing animals (*12, 30–32*), removal of suppressor cells by mechanical means (*33, 34*) or by pretreatment of the host (*33, 35, 36*), isolation of lymphoid cell-infiltrating tumors (*37–41*), chemical modification or pretreatment the effector cell (*27, 33, 34, 42, 43*) or stimulator cell (*33, 43, 44*), or enhancement of the generation of cytotoxic cells with the use of soluble factors obtained from lymphoid cells (*21, 32, 45–47*).

It has been previously shown that LF-TCGF can cause the proliferation of previously activated cytotoxic T-lymphocytes (*48, 49*) and can actively enhance the cytotoxicity of T-cells sensitized in its presence (*50, 51*). Although we have been unable to consistently generate cytotoxic lymphoid cells against the syngeneic FBL-3 murine lymphoma in C57BL/6 mice by conventional techniques, the in vitro expansion of in vitro sensitized cells in LF-TCGF has enabled us to develop lymphoid cell lines with a high degree of specific cytotoxicity for this syngeneic lymphoma. The cloning of these cytotoxic cells with the use of limiting-dilution techniques has enabled us to generate cloned cell lines with specific cytotoxicity for fresh tumor at effector-to-target ratios of 0.01–1 in short-term in vitro cytotoxicity assays, with maintenance of this reactivity after growth for several months in vitro.

These techniques for the generation and cloning of cytotoxic lymphoid cells directed against syngeneic tumor may be applicable to the generation of cytotoxic cells directed against other murine and human tumors for studies of host responses to tumor antigens and perhaps for the adoptive immunotherapy of tumors.

MATERIALS AND METHODS

Animals.—Adult C57BL/6 female mice were obtained from The Jackson Laboratory, Bar Harbor, Maine.

Tumors.—FBL-3 is a Friend virus-induced syngeneic lymphoma-leukemia that is transplanted in its ascitic form. This tumor was supplied to us by Dr. C. C. Ting, National Cancer Institute. This tumor shares tumor-specific and/or viral antigens that cross-react with other tumors induced by Friend, Moloney, and Rauscher viruses (*52*).

MCA-103 is a sarcoma in C57BL/6 mice that was induced in our laboratory by the injection of 0.1 ml of 1% 3-methylcholanthrene in sesame oil into the hindlimb as previously

described (*53*). It was maintained by serial im passage and was used in these experiments in transplant generations 4–7.

In vivo immunization.—Adult C57BL/6 female mice were given two weekly ip injections of 2×10^7 FBL-3 tumor cells irradiated with 10,000 R. After 6 weeks, spleen cells were harvested and used for in vivo or in vitro experiments.

Spleen cell suspension.—Spleens were removed aseptically, pooled, teased apart with two sterile forceps, and then passed through a single layer of 100-mesh nylon in HBSS. The cells were centrifuged at 500×*g* for 5 minutes, and the cell pellet was resuspended in buffered ammonium chloride solution for 1 minute at room temperature to lyse the red blood cells. The cells were washed three times and resuspended in CM. CM was composed of RPMI-1640 medium (Grand Island Biological Co., Grand Island, N.Y.) supplemented with 0.03% fresh glutamine (NIH Media Unit, National Institutes of Health), 1 μM sodium pyruvate (M.A. Bioproducts, Walkersville, Md.), 0.1 mM nonessential amino acids (M.A. Bioproducts), 5×10^{-5} M 2-mercaptoethanol, 100 U penicillin/ml, 100 µg streptomycin/ml, and 10% heat-inactivated FCS (Grand Island Biological Co.).

In vivo assay of in vivo immunized cells.—An adoptive chemoimmunotherapy model developed by Fass, Fefer, and coworkers (*54–56*) was used. Female 12-week-old C57BL/6 mice were given ip inoculations of 10^7 live FBL-3 tumor cells on day 0. By day 5, tumor cells could be found in the blood and lymph nodes and would have killed the animals if they were not treated. On day 5, mice were treated with 180 mg Cy/kg body weight, alone or in combination with ip administration of normal C57BL/6 lymphocytes or in vivo sensitized lymphocytes. Survival of mice was checked daily.

Production of LF-TCGF.—Optimal conditions for the production of LF-TCGF have been previously described (*51*). Single cell suspensions were prepared from spleens of exbreeder DBA/2 or BALB/c mice. A splenocyte preparation (50 ml) at a concentration of 4×10^7 cells/ml was incubated in 50-ml tubes (#2070; Falcon Plastics, Los Angeles, Calif.) with 10 µg Con A/ml (Miles Chemical Co., Elkhart, Ind.) at 37°C, in a 5% CO_2 atmosphere for 2 hours. The cells were then washed three times with HBSS, the pellet was resuspended in 50 ml CM without Con A, and 2 ml of the washed cell suspension was placed into individual wells of 24-well Costar plates (#3524; Cambridge, Mass.) and cultured for an additional 24 hours. Supernatants from these cultures were harvested, centrifuged, and passed through 0.45 filters (Millipore Corp., Bedford, Mass.). LF-TCGF supernatants prepared in this manner were more than 95% Con A-free as determined by absence of mitogenic activity on fresh lymphocytes and by measurement of removal of radiolabeled Con A.

IVS.—Stimulator cells were irradiated in a gamma irradiator with 10,000 R (FBL-3) or 2,000 R (normal C57BL/6 lymphocytes). Viable responder cells (6×10^7) and irradiated stimulator cells (1×10^6) were added to upright flasks (#3013; Costar) in a 20-ml total volume of CM (for generation of clones—*see* below) or 10 ml CM and 10 ml LF-TCGF (for generation of the whole population for expansion). Cells were harvested for expansion or in vitro tests on day 5. Yield of viable cells was approximately 25–31% of the initial concentration of responder cells.

Secondary IVS were performed by addition of 6×10^6 viable cells recovered from primary IVS on day 10 and 3×10^5 fresh irradiated tumor cells (or normal lymphocytes) to 24-well flat-bottomed plates (Costar) in 2 ml fresh CM. Tertiary IVS were performed in the same fashion on day 20 with the use of fresh CM and stimulators in exactly the same culture conditions as for secondary IVS.

Expansion of IVS lymphoid cells.—Cells were harvested from LF-TCGF flasks, centrifuged, and resuspended in fresh CM. Cell viability was assessed by trypan blue dye exclusion. These sensitized cells were adjusted to a concentration of 10^5 viable cells/ml in CM and then diluted in an equal volume of LF-TCGF (final concentration of 5×10^4 viable cells/ml). Of this final cell suspension 100 ml was placed in 750-ml tissue culture flasks (#3028; Falcon) lying flat, or 2 ml was placed in flat-bottomed tissue culture plates (#3524; Costar). The cells expanded sevenfold to tenfold in 6 days.

Cloning of IVS lymphoid T-cells.—Clones were generated with the use of a limiting-dilution technique in 96-well plates (#3596; Costar) from cells from primary, secondary, or tertiary IVS. Varying numbers of viable cells were plated per well (*57*).

^{51}Cr release cytotoxicity assays.—An 18-hour ^{51}Cr release assay was used under conditions previously described (*58*). Varying ratios of effector cells were plated in 96-well round-bottom plates (Linbro Titertek; Flow Laboratories, McLean, Va.) Viable fresh tumor targets (10^7) were labeled with 200 µCi of ^{51}Cr for 45 minutes at 37°C and in 5% CO_2. These targets were then washed three times, resuspended in RPMI-1640 medium and 10% heat-inactivated FCS, and plated at 10^4 viable cells/well. The plates were then centrifuged at 800×*g* for 5 minutes and kept at 37°C and in a 5% CO_2 atmosphere for 18 hours. The plates were then centrifuged at 2,000×*g* for 10 minutes and the supernatants harvested with the use of the Titertek Collecting System (Flow Laboratories).

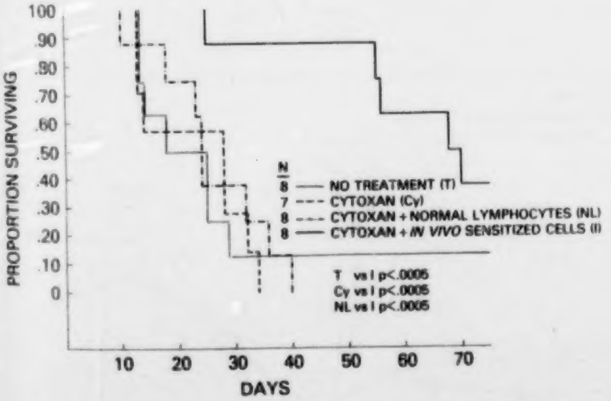
Fresh FBL-3 tumor was harvested for each assay, washed, and labeled. One MCA-103 tumor was minced with fine scissors, trypsinized for 7 minutes, passed through a double layer of 100-mesh nylon, then washed three times, and freshly labeled. Spontaneous release was not greater than 50% in any experiment.

Screening assay to assess cytotoxicity of clones.—Clones were screened for cytotoxicity with the use of a replica-plating technique. Of the contents of each well of a 96-well plate (#3596; Costar), 0.1 ml was replica transferred to a fresh 96-well plate. Then 0.1 ml of the target suspension containing 10^4 ^{51}Cr-labeled targets (labeled as above) was added to each well. The second replica plate was centrifuged, incubated for 18 hours, recentrifuged, and harvested as above. The original plate had fresh LF-TCGF added (1:1 concentration of LF-TCGF and CM) and was available for further study and continuous growth. Clones that appeared "interesting" and required further growth were then transferred to the 2-ml flat-bottomed plates (Costar) in a 1:1 concentration of LF-TCGF and CM and expanded.

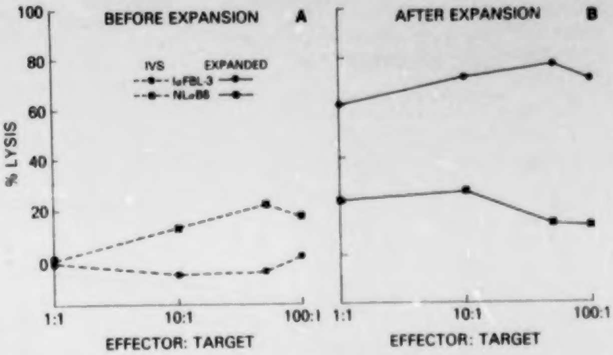
RESULTS

In vivo immunization against FBL-3 tumor.—Mice were immunized in vivo by two weekly ip injections of irradiated tumor cells. In multiple experiments, lymphocytes from these animals did not exhibit in vitro cytotoxicity in an 18-hour ^{51}Cr release assay (data not shown). These cells, however, were immune when tested by an adoptive transfer in vivo assay. A representative experiment is seen in text-figure 1. When compared to the transfer of spleen cells from normal mice, adoptive transfer of in vivo immunized lymphocytes conferred significant survival benefit. In all experiments combined, 53% of mice receiving Cy with in vivo immunized lymphocytes were cured (20/38) compared to 0 of 40 mice cured when mice were treated with Cy and normal lymphocytes or Cy alone (0/31 cured; $P<0.0005$ by paired log rank analysis).

In vitro cytotoxicity before and after expansion in LF-TCGF.—In an attempt to generate cells that exhibit cytotoxicity in vitro, in vivo sensitized lymphocytes were resensitized to irradiated FBL-3 cells in vitro for 5 days in the presence of LF-TCGF. Simultaneously, normal C57BL/6 lymphocytes were cocultured with normal C57BL/6 lymphocytes under identical conditions. Text-figure 2 shows a representative experiment. Both groups exhibited insignificant lysis of a fresh FBL-3 tumor in an 18-hour ^{51}Cr release cytotoxicity assay in six of eight experiments (text-fig. 2A). In the other two experiments low levels of lysis of fresh FBL-3 tumor were demonstrated only by the in vivo immunized lymphocytes resensitized to FBL-3 tumor and only at the effector-to-target ratio of 100:1 (data not shown). In eight of eight experiments, however, when these same IVS cells were expanded in LF-TCGF, there was a dramatic increase in cytotoxicity versus that seen with the fresh FBL-3 tumor only by the immunized cells (text-fig. 2B). Nonimmune cells cocultured with normal lymphocyte stimulators and then expanded in LF-TCGF showed low levels of lysis of fresh FBL-3 that did not change when they were expanded in LF-TCGF. When immune cells resensitized to FBL-3 tumor in vitro were expanded in LF-TCGF, lysis of fresh FBL-3 increased markedly (60% lysis at effector-to-target ratio of 1:1).

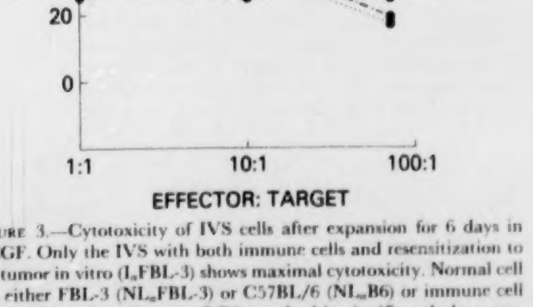


TEXT-FIGURE 1.—Survival of mice with disseminated FBL-3 lymphoma treated with in vivo immunized lymphocytes. When compared to treatment with Cy alone or Cy plus lymphocytes, treatment with Cy plus immune lymphocytes conferred significant survival benefit. All mice surviving at 75 days survived for >6 mo without tumor.

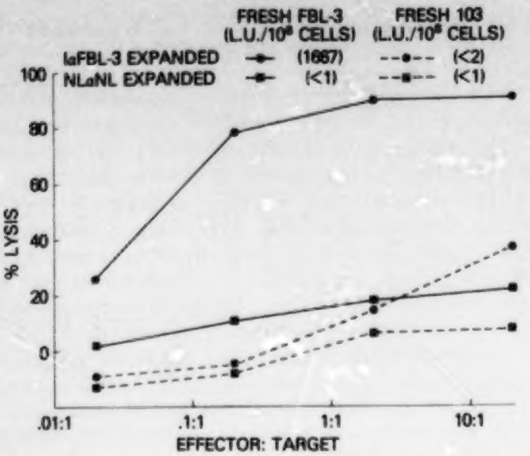


TEXT-FIGURE 2.—Cytotoxicity of IVS cells before and after expansion in LF-TCGF. A) No cytotoxicity after IVS; B) After expansion in LF-TCGF, only immune cells sensitized in vitro to FBL-3 tumor show significant cytotoxicity.

After expansion in LF-TCGF, only the combination of immune lymphocytes resensitized in vitro to irradiated FBL-3 tumor and then expanded in LF-TCGF showed this maximal lysis of fresh FBL-3 tumor (text-fig. 3). While the other three combinations of IVS (normal lymphocyte resensitized to FBL-3 tumor, immune lymphocyte cocultured with normal C57BL/6 lymphocytes, or normal nonimmune lymphocytes cocultured with normal lymphocyte stimulators) expanded in LF-TCGF showed some cytotoxicity of FBL-3, none had the same degree of lysis as immune lymphocytes cocultured with FBL-3 tumor. At an effector-to-target ratio of 1:1, maximal cytotoxicity was seen in the immune lymphocyte resensitized to FBL-3 tumor and then expanded in LF-TCGF. In subsequent experiments it was



TEXT-FIGURE 3.—Cytotoxicity of IVS cells after expansion for 6 days in LF-TCGF. Only the IVS with both immune cells and resensitization to FBL-3 tumor in vitro (I_{α}FBL-3) shows maximal cytotoxicity. Normal cell IVS to either FBL-3 (NL_{α}FBL-3) or C57BL/6 (NL_{α}B6) or immune cell IVS to C57BL/6 lymphocytes (I_{α}B6) resulted in significantly less cytotoxicity.



TEXT-FIGURE 4.—Specificity of lysis in a ^{51}Cr release assay. Whole populations of immune lymphocytes resensitized in vitro to FBL-3 tumor and then expanded in LF-TCGF exhibited significant cytotoxicity to fresh FBL-3 tumor but not to fresh syngeneic MCA-103 tumor.

necessary to reduce the effector-to-target ratio to 0.01:1 to reduce this lysis to near base-line levels.

Specificity of tumor lysis.—Immune lymphocytes resensitized in vitro to irradiated FBL-3 tumor and then expanded in LF-TCGF were tested for lysis of the FBL-3 tumor and a non-cross-reactive syngeneic MCA-103 tumor in the same assay. Lysis of fresh FBL-3 tumor but not MCA-103 tumor was seen in six of six experiments (text-fig. 4). Table 1 shows a representative experiment in which the immune cells cocultured with FBL-3 tumor and then placed in LF-TCGF had an 8,000-fold expansion and maintained their specific, high levels of cytotoxicity.

For a test of the relative ability of fresh FBL-3 and fresh MCA-103 targets to lyse, DBA/2 lymphocytes were sensitized in vitro to irradiated C57BL/6 lymphocytes in LF-TCGF. Text-figure 5 shows the in vitro lysis of FBL-3, MCA-103, and C57BL/6–Con A blasts at 4 hours and 18 hours when these allosensitized effectors were used. At both times the C57BL/6–Con A blast target demonstrated the most lysis. At 4 hours the relative abilities of fresh FBL-3 and fresh MCA-103 to lyse were equal (text-fig. 5A). At 18 hours these two targets again showed little difference in relative abilities to lyse (text-fig. 5B).

Screening assay for clones.—In all experiments described here, 10^3 cells per well were plated. There were 60 wells with growth of 288 wells plated from the immune sensitization and 121 wells with growth of 288 wells plated from the normal sensitization. On the basis of the Poisson distribution, the chance that growth in a single well arose from a single cell from the immune sensitization was 90% and the chance that growth was from a single cell from the normal sensitization was 75%.

With the use of the screening assay described in "Materials and Methods," we screened all clones from each

TABLE 1.—*Expansion of immune cells with maintenance of specific high-level cytotoxicity after coculture with FBL-3 tumor cells and subsequent placement in LF-TCGF*[a]

Day of expansion	I$_a$FBL-3[b]				NL$_a$NL[c]

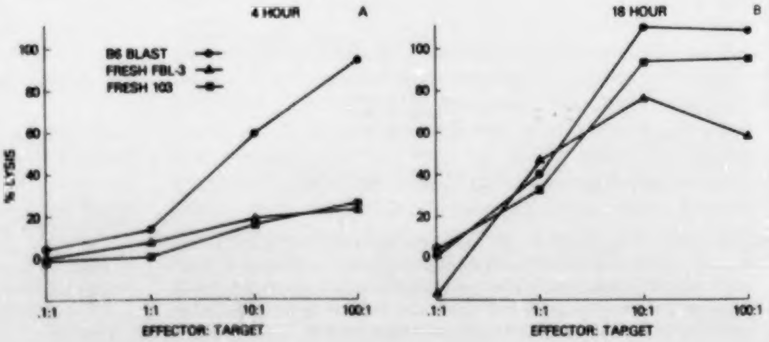
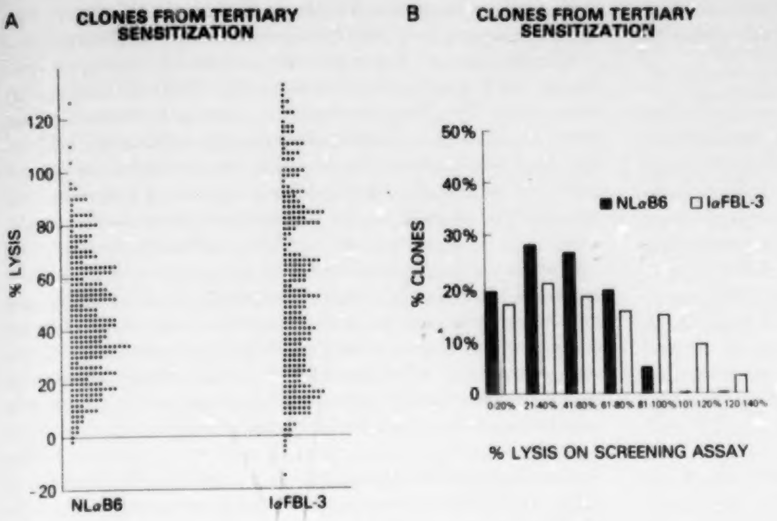
[b] I$_a$FBL-3=in vivo immunized lymphocytes resensitized to FBL-3 tumor in vitro.

[c] NL$_a$NL=Normal C57BL/6 splenocytes resensitized to normal C57 irradiated stimulators in vitro.

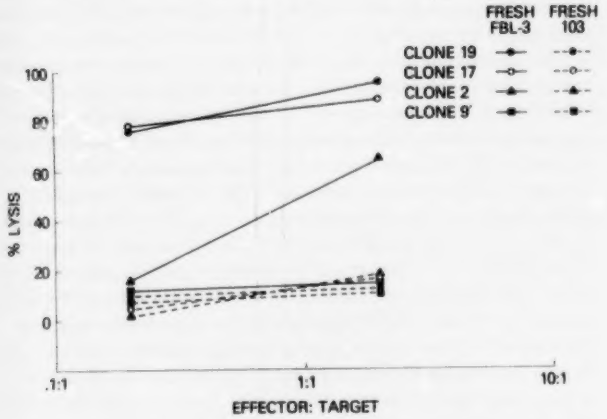
[d] On day 26, cells were split to one-half concentration and fed with fresh CM and LF-TCGF.



TEXT-FIGURE 5.—Relative ability of fresh FBL-3 and MCA-103 tumors to lyse. An IVS of DBA/2 lymphocytes stimulated with irradiated C57BL/6 splenocytes was used. There is no difference in the inability to lyse of fresh FBL-3 tumor when compared to fresh MCA-103 tumor, at either 4 or 18 hr. B6=C57BL/6.



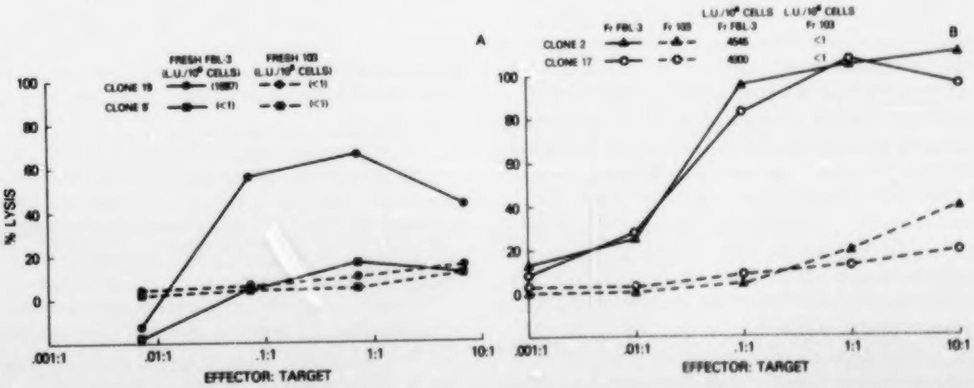
TEXT-FIGURE 6.—Results of a rapid screening assay for cloned lymphoid cells with the use of FBL-3 target cells. A) Results of one assay in which *each dot* represents an individual clone. B) The same data as a percentage of the total number of clones.



TEXT-FIGURE 7.—Cytotoxicity of several clones at known effector-to-target ratios after 1 mo in LF-TCGF. Clones 19, 17, and 2 were specifically lytic for fresh FBL-3 tumor cells and not for fresh MCA-103 tumor cells. Clone 9′ (from an IVS of normal lymphocytes resensitized to normal lymphocytes) is not lytic for either target.

IVS at a single time. Text-figure 6A shows the results of screening clones from the tertiary IVS. Each dot represents one clone. The highest proportion of lytic clones resulted from the in vitro sensitization of the immune lymphocytes with FBL-3 tumor. The distribution of lytic clones is shown in text-figure 6B. Approximately 15% of the total number of clones from the immune cells cocultured with FBL-3 tumor in vitro had cytotoxicity more than 100% in our screening assay, whereas none of the control lymphocytes produced clones with this degree of lysis.

Specificity of clones in an 18-hour ^{51}Cr release assay.—From these screens three cytotoxic clones and one noncytotoxic clone were selected for further study. Text-figure 7 shows that clones 2, 17, and 19 (cytotoxic clones) but not clone 9′ (the noncytotoxic clone) were specifically cytotoxic for the fresh FBL-3 tumor but not for the MCA-103 tumor at 1 month. This specific, high degree of cytotoxicity was maintained for 2.5 months. Text-figure 8 shows two assays testing these same four clones against both fresh syngeneic tumor targets. Again, the cytotoxic clones 2, 17, and 19 had extremely high specific cytotoxicity (up to 4,545 LU/10^6/



TEXT-FIGURE 8.—Clones from text-figure 7 tested after 2.5 mo of continuous growth in LF-TCGF. A) Clone 19 is shown to be specifically lytic for fresh FBL-3 cells. Clone 9′ does not lyse either fresh FBL-3 or fresh MCA-103 tumor cells. B) Clones 2 and 17 are both highly lytic for fresh FBL-3 cells.

cells) compared to less than 1 LU for the noncytotoxic clone 9′. At no time did any of these clones lyse the fresh syngeneic MCA-103 target.

DISCUSSION

Many workers attempted to utilize in vitro sensitization techniques for the generation of cytotoxic lymphoid cells against tumors or tumor antigen (*2–21*). Macrophage presentation of tumor (*4, 6, 10, 24, 25*) and removal of suppressor cells (*33–36*) have been found to be effective in generating cytotoxicity against tumors. Chemically modifying or pretreating the effector population has enhanced cytotoxicity (*27, 33, 34, 42, 43*), and modifying the stimulator population (*33, 43, 44*) similarly has increased cytotoxicity in selected tumor systems. Cytotoxicity has been generated against tumor antigens with the use of peritoneal exudate cells (*13, 26–28*), cells from tumor-bearing animals (*12, 30–32*), cells from in vivo immunized animals (*7–10, 12–15, 17, 27, 29*), and lymphocytes infiltrating the tumor itself (*37–41*).

Helper factors produced by lymphoid cells have also been used to successfully enhance the in vitro generation of cytotoxicity against syngeneic tumors. Kilburn et al. (*45*) described the isolation of a helper factor that enhanced the generation of cytotoxic cells to P815 syngeneic tumor. Similarly, Reyser et al. (*46*) described a supernatant product of a secondary allogeneic mixed lymphocyte culture that, when added to a primary mixed leukocyte–tumor cell culture, increased lytic activity against the syngeneic tumor target. In addition, these authors found the same effect when supernatants from Con A-stimulated spleen cells were added to primary mixed leukocyte–tumor cell cultures.

Since the description by Gillis and Smith (*59*) of long-term culture of tumor-specific cytotoxic T-cells, much work has gone into attempts to grow and maintain cytotoxic T-cells and clones with the use of TCGF. We have previously noted (*51*) a marked enhancement of the generation and expansion of cytotoxic cells attributable to LF-TCGF in allogeneic in vitro sensitizations. Baker et al. (*60*) showed that long-term growth of clones generated from IVS cultures was possible with the use of TCGF with maintenance of specific cytotoxicity. More recently, TCGF has been used during in vitro sensitization of spleen cells from mice bearing the P815 syngeneic mastocytoma to generate high levels of cytotoxicity against the syngeneic tumor target (*32*). Cheever et al. (*47*) also used TCGF to expand cells from an in vitro sensitization of in vivo immunized lymphocytes resensitized to irradiated tumor. They achieved specific cytotoxicity against the cultured syngeneic tumor target.

In the studies reported in this paper we have attempted to generate lymphoid cells highly cytotoxic for the transplantable FBL-3 lymphoma, syngeneic in C57BL/6 mice. Fresh splenocytes from mice immunized to fresh FBL-3 tumor exhibited no in vitro cytotoxicity toward FBL-3 either before or after cocultivation with FBL-3 in vitro. Our results thus differed from those of Cheever et al. (*61–63*) who reported that immune splenocytes were cytotoxic for FBL-3 after in vitro incubation with this tumor. Cheever et al. utilized cultured tumor target cells, however, whereas in all of our experiments we have used tumor cells obtained fresh from the ascites of tumor-bearing mice. Culture of the FBL-3 tumor in xenogeneic serum, as performed by others, may lead to alterations in the lytic susceptibility of these cells.

We did, however, consistently generate cells highly lytic for the FBL-3 tumor by cocultivating cells from immunized mice with FBL-3 tumor cells in vitro and then exposing them to LF-TCGF. This technique generated cells exhibiting high levels of lysis in all eight experiments. The generation of lytic cells required both an in vivo immunized lymphocyte population and a reexposure to the tumor in vitro prior to growth in LF-TCGF (text-figs. 2, 3). Lymphocytes from nonimmune mice cocultivated with FBL-3 or lymphocytes from immune mice cocultivated with normal C57BL/6 splenocytes resulted in much less lysis of fresh FBL-3 tumor when grown in LF-TCGF (text-fig. 3). Cytotoxic lymphoid cells generated by this technique were capable of progressive exponential proliferation for up to 3 months with maintenance of cytotoxicity (text-fig. 4).

Lymphoid cells lytic for FBL-3 were not capable of lysing a non-cross-reactive syngeneic tumor, MCA-103 (text-fig. 4, table 1). Both tumors exhibited approximately the same lysis, however, when they were used as targets for DBA/2 lymphocytes sensitized in vitro to irradiated C57BL/6 lymphocytes (text-fig. 5).

The generation of cells lytic for FBL-3 tumor by growth in LF-TCGF is consistent with the hypothesized role of TCGF as a "second signal" in the generation of immune responses. Spleens obtained 6 weeks after immunization with the FBL-3 tumor probably contain small numbers of memory cells with receptors for FBL-3 tumor. Reexposure of these cells to FBL-3 tumor in vitro results in the activation of this small subpopulation of T-cells, although the number of activated cells is too small to cause consistent lysis (two of eight experiments) of FBL-3 in vitro. Growth of this cell suspension in LF-TCGF appears to result in selective expansion of the activated cells and not of the resting lymphocytes. Expansion could be accomplished in the absence of activating antigen in culture, similar to the findings of others (*50, 64, 65*), probably mediated by the binding of this lymphokine to activated T-cells (*66*). This hypothesis accounts for the requirements of both an in vivo immunized starting cell and a reexposure to the specific tumor cell in vitro prior to expansion in LF-TCGF.

The presence of only a small number of highly reactive cells following in vitro sensitization was also seen in our studies of the generation of cloned lymphoid lines after reexposure of immunized cells to FBL-3 in vitro (text-fig. 6). Only about 5% of immune lymphoid clones are more highly lytic for FBL-3 than clones from nonimmunized cultures (text-fig. 6).

The cytotoxic expanded cultures were totally dependent on the continued presence of TCGF. We have been able to maintain cultures in exponential growth for over 3 months without the "crisis" period described by others (*47, 67*). Cell growth and maintenance of cytotoxicity were not dependent on the continued presence of antigen (tumor cells).

The screening technique for cytotoxic clones that we have described has enabled us to select rare, highly cytotoxic cells for further study. The initial testing of cells directly from the limiting dilution plates is conducted at unknown effector-to-target ratios and results in an inherent advantage to rapidly growing cells. This technique might miss slowly growing, highly cytotoxic clones that are represented by very few cells. Suitable clones can then be selected and grown in LF-TCGF with maintenance of antitumor cytotoxic specificity for over 2.5 months (text-figs. 7, 8). On the basis of probabilities of cell distribution according to the Poisson distribution, the clones we have described have an 80% chance of having arisen from a single cell. These "clones" have now been "recloned" to increase the probability of derivation from a single effector cell.

When compared to the use of bulk T-cell cultures, the use of a cytolytic T-cell clone for studies of the cellular immune response to tumors offers several advantages. Presumably, all cells derived from cytolytic clones are themselves lytic. Moreover, the cloning of cytolytic cells provides the opportunity to remove suppressor or other modulator cells that might abrogate the effect of cytolytic T-cells on target tumor cells.

A potential problem exists in the selection of cells to be used in adoptive immunotherapy on the basis of in vitro reactivity in ^{51}Cr release cytotoxicity assays. In vivo effect may not correlate with the results of in vitro assays and in fact the primary effector cell in vivo may be a cell type other than a cytotoxic cell (i.e., helper cell). Indeed, this could explain why in vivo immunized cells (text-fig. 1) are effective in eradicating a tumor in vivo but demonstrate no cytotoxicity in vitro. This hypothesis is supported by the findings of Fernandez-Cruz et al. (*68*), who showed that the subset of T-cells most effective in in vivo tumor eradication was the least cytotoxic in an in vitro ^{51}Cr release assay. In experiments to be presented elsewhere, we have shown that adoptive transfer of lytic cells expanded in TCGF is effective in curing mice with disseminated FBL-3 lymphoma.

The methods described in this paper have been very effective in generating and maintaining cytotoxic effector cells directed against the syngeneic FBL-3 lymphoma. Further study of cytotoxic clones will be useful in the elucidation of tumor-effector cell interactions both in vitro and in vivo.

Pathogenesis of Lesions Induced in Rat Lung by Chronic Tobacco Smoke Inhalation[1,2,3]

Carol A. Heckman, *Ph.D.,*[4] *and* **Walden E. Dalbey**, *Ph.D.*[4,5]

ABSTRACT—Lesions were induced in the lungs of specific-pathogen-free F344 rats by chronic tobacco smoke exposure. Animals exposed to 7 cigarettes/day were killed after 1, 1.5, or 2 years of exposure. Parallel lifetime exposures induced pulmonary tumors in 9% of the animals. In serially killed animals, four types of lesions were found: 1) perivascular or peribronchiolar accumulation of lymphoreticular cells, 2) fibrotic and cellular enlargement of peribronchiolar septa, 3) type II cell hyperplasia with septal fibrosis, and 4) air-space enlargement (emphysema). However, emphysema occurred only in animals exposed to a higher (10 cigarettes) dose of tobacco smoke. Ultrastructural studies showed all of the focal lesions to be infiltrated by cells typical of the inflammatory response. The type II hyperplastic and peribronchiolar alveolar lesions involved larger portions of the parenchyma in fibrotic changes but differed in structure, location, and frequency. The incidence of the peribronchiolar alveolar lesions was temporally related to tumor incidence.—JNCI 1982; 69:117–129.

Numerous previous reports have described the effects of tobacco smoke exposure on lung structure. In studies by Roe's group (*1, 2*), the major lesions induced in the rat lung by lifetime exposure were columnar, cuboidal, and squamous metaplasias of the alveolar epithelium. All three types of lesions were significantly more frequent in smoke-exposed than in control animals (*1*) and could be induced by intratracheal instillation of smoke condensate (*2*). However, neoplasms could be induced only by intratracheal instillation of the polycyclic aromatic hydrocarbon-containing fraction of smoke condensate (*2*). No statistically significant increase in pulmonary neoplasm incidence was found in animals exposed to smoke by inhalation, presumably because the animals died prematurely from chronic respiratory disease (*1*).

Short-term studies conducted independently by Walker et al. (*3*) on rats exposed to tobacco smoke for 6 weeks showed characteristic lesions at the level of the respiratory bronchiole, including peribronchiolar and perivascular infiltration by lymphocytes, focal pneumonitis, and alveolar cuboidal or columnar metaplasia. The metaplastic changes, along with increases in macrophage size and number, were thought to be dose-dependent. The other lesions were considered early manifestations of chronic pulmonary infection (*3*). Morphologic changes have also been induced in the lungs of beagle dogs by 2–5 years of tobacco smoke exposure (*4*). Marked fibrosis and emphysema were found, as were type II cell hyperplasia and squamous metaplasia of the alveolar epithelium. At the epithelial–mesenchymal interface, projections of the epithelial cells into the stroma and thickening and reduplication of the basal lamina (*5*) were also seen.

Despite the substantial number of experiments with chronic tobacco smoke inhalation, only two laboratories have reported significant induction of pulmonary tumors in exposed rodents. One report showed a twofold higher incidence of adenocarcinomas in smoke-exposed mice than in control mice. The gas phase of the smoke was found to induce an even higher tumor incidence than the whole smoke (*6*). More recently, a lifetime exposure of rats to tobacco smoke produced a 9% incidence of respiratory tract tumors, including adenomas, adenocarcinomas, and squamous cell carcinomas (*7*). In this experiment, animals exposed in parallel with those for the lifetime study were killed at earlier intervals for assessment of morphologic lesions induced by smoke inhalation. The present report characterizes those lesions. Many of the alterations appeared to be similar to those described above. However, 1 lesion was found that had not been found in previous experiments, i.e., fibrotic thickening of alveolar septa in peribronchiolar locations.

MATERIALS AND METHODS

Exposure conditions.—SPF female F344 rats were exposed to tobacco smoke in the Maddox/ORNL smoking machine as previously described (*7*). Beginning at 12–14 weeks of age, the animals were gradually exposed to increasing dosages of tobacco smoke from standard 85-mm, nonfiltered experimental cigarettes (National Cancer Institute code 16). Two final dose levels were used, 7 or 10 cigarettes/day, and the animals were killed at time intervals from 1 to 2 years after exposure began. The exact number of animals killed at various times in each dose group is shown in table 1. Since mortality was high in the 10-cigarette-per-day group, all the remaining animals in this group were killed at 1.5 years. Both untreated and sham-exposed groups were killed in parallel with the exposed animals. Additional data were

TABLE 1.—*Number of animals used for morphogenesis studies*

Duration of smoke exposure, yr	No. of animals			
	Treatment group: Untreated	Sham treated	7 cigarettes/day	10 cigarettes/day
1.0	10	10	10	8
1.5	9	9	9	14
2.0	10	12	11	0
2.5	2	4	6	0

obtained from animals in the lifetime study; these rats were killed after exposure for 2.5 years and maintenance for an additional 7 months without exposure. One animal from each treatment group was tested for infective organisms. Blood samples were tested by Microbiological Associates, Bethesda, Md., for the presence of serum antibodies to several viruses: PVM (pneumonia virus of mice), Reo-3 (reovirus type 3), GDVII (Theiler's mouse encephalomyelitis GDVII), k (newborn mouse pneumonitis, k-virus), polyomavirus, MVM (minute virus of mice), MHV (mouse hepatitis virus), Sendai virus, and RCV (rat corona virus). Cultures prepared from the postcaval lung lobe were tested for mycoplasma (*8*). All test results were negative.

Tissue preparation.—Before they were killed, the animals were anesthetized with 30 mg pentobarbital/kg body weight. For tissue fixation the trachea was cannalized; the airways and lungs were removed and fixed with buffered formaldehyde under 20 cm of pressure for 24–48 hours. The lung lobes were cut along the bronchus, except for the left lobe, which was cut in cross section just anterior to the entry of the bronchus. The tissues were embedded in paraffin. Sections from the right lobes were used to determine the number of fibrotic lesions in the lungs of smoke-exposed animals. All of the sections were examined, and the cumulative number of lesions, normalized to the number of animals killed, was used as an estimate of the frequency of each type of lesion. Sections from the left lobes, stained with hematoxylin and eosin, were used for morphometric analysis. For each sample, 10 fields were selected at random and viewed at 100× magnification through a Weibel ocular. Fields comprised of more than one-third conducting airways or vasculature were excluded. The mean linear intercept was determined, and point counts (420 points/lobe) were made to obtain the volume percent of alveolar versus nonalveolar air space and respiratory versus nonrespiratory tissue. Alveoli were defined as enclosed circles or as open semicircles with a radius greater than half the distance across the opening. Additional sections of the left lobes were stained with Snook's silver stain for reticulum, aldehyde fuchsin, and Lushbaugh's stain.

Each time rats were killed, tissues were also processed for electron microscopy by airway perfusion of a 2% glutaraldehyde solution containing 4.6% Tyrode's solution and 0.05 *M* collidine buffer (pH 7.3). The tissues were fixed for 2 hours under 15-cm pressure and retained in collidine buffer until further processing. After exposure to 2% osmium tetroxide in 0.1 *M* cacodylate for 3 hours, selected blocks of tissue were dehydrated in acetone and embedded in a standard epoxy mixture (*9*). Sections 2 μm in thickness were cut on the Sorvall JB-4 microtome and stained with 0.05% toluidine blue in 2.5% sodium carbonate. Selected areas of the blocks were thin sectioned on the Sorvall MT-2 ultramicrotome, mounted on Formvar-coated grids, and stained with uranyl acetate and lead citrate (*10*). Thin sections were examined with the Siemens 101 or Hitachi HU-11B electron microscope. For each pathologic change studied, at least four examples were examined ultrastructurally.

RESULTS

Some changes in the lung parenchyma following smoke exposure were readily apparent on a gross level. Lungs from animals exposed to 7 cigarettes/day for 1 year had dark foci about 1 mm in diameter scattered over their surfaces. With longer exposures or with exposure to 10 cigarettes/day, there were increasing numbers of larger white nodules about 1–4 mm in diameter. Four types of lesions could be distinguished microscopically in the pulmonary parenchyma: 1) perivascular or peribronchiolar accumulation of lymphoreticular cells, 2) fibrotic and cellular enlargement of peribronchiolar septa, 3) type II cell hyperplasia with septal fibrosis, and 4) air-space enlargement (emphysema). The first type of lesion was most common in the lungs of animals exposed to 7 cigarettes/day for 2 years. The last lesion type was seen only in animals exposed to 10 cigarettes/day.

Perivascular or Peribronchiolar Cell Accumulation

Perivascular lesions occurred frequently in the lung parenchyma after 2 years of smoke exposure, averaging 3 lesions/section of approximately 0.5 cm^2. The frequency after a 2-year exposure was approximately double that after a 1-year exposure. The lesions were characteristically associated with venules and arterioles in the parenchyma. They were most common in branches of the pulmonary vein located at or below the level of the terminal bronchiole (figs. 1A, 1B) and were also found in bronchial veins, but they were never seen in the adventitia of major arteries. Perivascular accumulations of cells were also found rarely in unexposed rats and consisted of large lymphocytes and macrophages (fig. 1C). The lesions of smoke-exposed lung tissues contained predominantly particulate-laden macrophages (figs. 1A, 1B). An ultrastructural analysis of several lesions associated with venules showed that lymphocytes, plasma cells, and, occasionally, fibroblasts were closely apposed to macrophages in the adventitia (fig. 2). While macrophages and lymphocytes were usually seen adjacent to the basal lamina of the epithelium, the cell mass was separated from the epithelium by a basement membrane in some lesions. In addition to the adventitial lesions, a separate lesion was sometimes found around major veins, consisting of lymphocytes within the lumen of lymphatic vessels. The lymphatic endothelium in these lesions frequently contained smoke particulates (figs. 3A, 3B). However, lesions with characteristics intermediate between those of the lymphatic and adventitial lesions were not found, so a common etiology seemed unlikely.

Lesions similar to the other adventitial perivascular lesions were also found near the bronchiolar–alveolar junction, most frequently between the bronchiole and the bronchial vein and extending only part of the way around the bronchiole. Therefore, most of these lesions were also perivascular in location.

Fibrotic and Cellular Enlargement of Peribronchiolar Septa

Septal enlargement was characteristic in peribronchiolar locations, but it was also found in type II hyperplasias. The enlarged septa in both lesions had similar ultrastructural features. Generally, both histologic types of lesions were larger than perivascular lesions and could be discerned readily in paraffin-embedded lung tissue. Neither type of lesion was found in the lungs of control animals, and the frequency of both types increased with the number of cigarettes smoked and the cumulative time of smoke exposure (table 2). The type II hyperplastic lesions always constituted more than 90% of the total number of large lesions. However, the total number of peribronchiolar lesions increased markedly in the later stages of exposure at a dose of 7 cigarettes/day. In animals exposed at the higher dose rate of 10 cigarettes/day for 1.5 years, the peribronchiolar lesions constituted only 2% of the large lesions, even though the cumulative dose of tobacco smoke was comparable to that delivered in the 2-year exposure at the lower dose rate. The peribronchiolar lesions constituted 7% of the large lesions under the latter conditions. In paraffin-embedded sections treated with Lushbaugh's stain for collagen, the amount of collagen seen in lesions showing septal enlargement appeared to increase in relation to the dose of tobacco smoke. No obvious increases in reticular fibers (Snook's silver stain) or elastic fibers (aldehyde fuchsin) were observed.

Although the two types of lesions exhibiting septal enlargement differed in location, frequency, and the type of lining epithelium present, the septal constituents were similar when examined ultrastructurally. Peribronchiolar lesions were characterized by an attenuated epithelium (fig. 4A) and by distortion of the normal semicircular profile of the alveoli (fig. 4B). In extreme cases, the septa were fused into a single mass. About half of the enlargement lesions in peribronchiolar locations also showed alveolar bronchiolization (fig. 4C), and a new columnar epithelium frequently appeared to extend into the alveolar duct (fig. 4A). Although septal thickening may also have occurred in loci separate from larger lesions, this was evidently rare; a few areas where enlargement was seen in isolation from neighboring lesions were found by serial sectioning to be adjacent to lesions. Type II hyperplastic lesions were observed most frequently at the pleura (figs. 5A–5C) but were also in the lung parenchyma adjacent to the distal airways (fig. 1B). In animals exposed to a dose of 7 cigarettes/day for 1 or 2 years, about 60% of the lesions were located on the pleura. When pleural lesions embedded in epoxy resins were serially sectioned, nearly all of them were found to be adjacent to sites where one or more alveolar ducts terminated on the pleura; about half were also distal to or surrounding perivascular lesions (fig. 5B). Fibrosis was obvious at the light microscopic level in the alveolar septa of all type II cell lesions.

The septal enlargements studied by electron microscopy contained numerous cells of the lymphoreticular system, i.e., plasma cells, lymphocytes, polymorphonuclear leukocytes, macrophages, and mast cells. Fibroblasts were also seen in all of the lesions and frequently appeared hypertrophic relative to those in unaffected septa (fig. 6). There were also extensive bundles of collagen fibers within the interstitium. Capillaries within the septa had swollen or hypertrophic endothelial cells that frequently occluded the lumen. In other areas the basal lamina showed extensive thickening, infolding, or reduplication (fig. 6).

The largest peribronchiolar lesions exhibited an aberrant morphology in which lengths of the basal lamina were completely surrounded by lymphoreticular cells, indicating areas of probable fusion of adjacent septa. Although the cellular constituents were similar to those in smaller lesions, they included fragments of cells embedded in an amorphous extracellular material resembling fibrin (fig. 7). These were thought to be derived from capillaries that were no longer patent. In densely fibrotic and cellular areas, there were relatively few capillaries of normal appearance. Both the squamous and type II epithelial cells in these areas sometimes contained an osmiophilic cytoplasm with an elaborate endoplasmic reticulum. Both epithelial cells and fibroblasts in these areas frequently contained osmiophilic granules resembling lipid droplets (fig. 7).

TABLE 2.—*Number and percent incidence of large lesions observed in lung after chronic tobacco smoke exposure*[a]

Duration of smoke exposure, yr	No. of large lesions and percent incidence			
	7 cigarettes/day		10 cigarettes/day	
	Peribronchiolar[b] (%)	Type II[b] (%)	Peribronchiolar[b] (%)	Type II[b] (%)
1.0	0.3±0.1 (33)[c]	9.1±2.6 ([illegible])[e]	0.1±0.1 (14)	11.6±3.0 (86)[f]
1.5	0.7±0.4 (43)[g]	17.4±3.4 (86)[e,h]	0.5±0.2 (42)	25.5±2.5 (100)[f]
2.0	1.9±0.4 (90)[c,g]	25.3±4.5 (100)[d,h]	—	—

[a] *P*-values for the peribronchiolar comparisons were derived by a conditional exact test. Corresponding values for the type II lesion comparisons were derived by *t*-tests.

Type II Cell Hyperplasia

The cellular and extracellular constituents involved in enlargement of the interstitium in type II hyperplastic lesions were similar to those described in the preceding section. All of the type II lesions studied showed some degeneration of basal lamina structure; in areas where marked degeneration occurred, the type I epithelium was separated from the underlying connective tissue (fig. 8). Degenerative changes were frequently, though not always, found in areas where luminal macrophages were in close contact with the type I epithelium. The presence of phagocytes (i.e., macrophages and polymorphonuclear leukocytes) in the interstitium had little relationship to the position of basal lamina degeneration. The lining epithelium in hyperplastic lesions consisted of cells with an undifferentiated appearance, which could be flattened, distorted in shape, or hypertrophic. Some of the cells showed long microvilli on their luminal surfaces. In addition, most lesions contained cuboidal, type III cells, with an extensive endoplasmic reticulum rather than the lamellar bodies typical of type II cells (fig. 9). Other type III cells had a dense cytoplasm, abundant profiles of endoplasmic reticulum, and osmiophilic inclusions (fig. 10). Lymphocytes were frequently found as cellular constituents of the epithelium. Binucleate cells and evidence of stratification in the epithelium were seen in about half of the lesions. A few lesions also contained large cells with an exceptionally clear cytoplasm (fig. 8).

Air-Space Enlargement

In addition to the focal lesions described above, we detected a general tendency for enlargement of the air space in animals exposed to a high dose of tobacco smoke for 1 year or more. This trend was indicated by an increase in the apparent nonalveolar air space. Although a similar trend was seen in the surviving animals of the low-dose group, it fell short of statistical significance. Exposure of animals to 7 cigarettes/day for up to 2.5 years did not significantly influence the mean linear intercept (table 3). However, exposure to 10 cigarettes/day had a more pronounced effect on lung architecture: The mean linear intercept was increased significantly above control levels at both 1 and 1.5 years of exposure (table 3).

DISCUSSION

We obtained the present results on tobacco smoke inhalation in parallel with a lifetime study that demonstrated the induction of several types of lung tumors by tobacco smoke (*7*). The animals were maintained under SPF conditions; thus the histopathologic interpretation of pulmonary lesions was not complicated by chronic lung disease, and survival was not compromised by infection. In the lifetime experiment, the observation of tobacco smoke-induced tumors clearly was dependent on the long-term survival of the experimental animals. The mean survival time (± SD) was 2.3±0.6 years for rats exposed to 7 cigarettes/day, 2.4±0.4 years for untreated controls, and 2.6±0.4 years for sham-exposed controls. The survival curves for these 3 groups were not significantly different. The earliest of the 5 adenomas found among the treated animals appeared at 2.0 years, and the average age at death of the animals with these tumors was 2.6 years. For the 5 other lung and nasal tumors, which were adenocarcinomas and a squamous cell carincoma, the average age at death was 3.1 years. Only 1 alveologenic carcinoma was observed in the control animals over their life-span. The final incidences of respiratory tract tumors were 9 and 1% in the experimental and control groups, respectively.

The present studies have shown that the most common type of focal lesions to develop in the lungs of tobacco smoke-exposed animals consisted of accumulated lymphocytes and macrophages in the vascular adventitia. Similar accumulations were also found in the lamina propria of terminal bronchioles, where some of them were continuous with lesions surrounding the bronchial veins or branches of the pulmonary veins. While all of the focal lesions were found to include cellular infiltrates typical of the inflam-

matory response, the cell types found in the vascular adventitia were typically restricted to lymphocytes and macrophages. Similar accumulations of lymphoreticular cells in perivascular locations have been noted in the normal course of aging in the rat (*11*) and in cases of multiple sclerosis in humans (*12*).

Although perivascular lesions were often contained within some of the more extensive lesions, it is not clear whether they played an essential role in the pathogenesis of the larger lesions. The larger lesions could have been induced by infiltration of lymphoreticular cells into the surrounding parenchyma or could have been initiated independently. Since these locations were probably subjected to tobacco smoke exposure under similar local conditions, inflammatory responses could have resulted from the same, presumably chemotactic, biochemical intermediaries in both cases. However, the larger lesions showed the full spectrum of inflammatory cells, including polymorphonuclear leukocytes and mast cells. Another feature common to the more extensive lesions was degradation of the basal lamina, particularly under the type I or squamous epithelial cells. We considered this alteration a possible contributing factor in fibrogenesis and/or epithelial hyperplasia. The proximity of phagocytes, particularly macrophages, to these sites suggested that enzymes released from the cells during phagocytosis may affect the structure of the lamina. The presence of lymphocytes, monocytes, and macrophages in the interstitium has also been reported in human diffuse interstitial lung diseases (*13*).

Lesions of comparable structure to the type II hyperplastic and peribronchiolar fibrotic lesions have been induced in many previous studies of lung pathology, but authors have tended to classify the cuboidal and columnar metaplastic lesions together. The exceptions that particularly note "bronchiolization" of the peribronchiolar alveoli have been reports on mice and hamsters infected with influenza virus (*14*), mice exposed to synthetic smog or calcium chromate dust (*15*), and hamsters treated with chemical carcinogens (*16*). In experiments on rats treated with various agents, particularly intratracheal instillation of tobacco smoke condensate (*2*) or of casein and carbon particulates (*17*), or a single exposure to benzo[*a*]pyrene followed by lifetime tobacco smoke inhalation (*1*), bronchiolization appeared to have occurred but to have been classified with other types of metaplasia. Our studies, based on the improved structural detail obtained by the examination of tissues embedded in epoxy resins, suggest that the bronchiolar lesions differ in several respects from the more common cuboidal metaplasias, which were identified here as type II hyperplasias. Since only about half of the peribronchiolar lesions showed epithelial metaplasia, our studies are also the first performed on rodents to suggest that fibrotic and cellular enlargement of the peribronchiolar septa precedes the replacement of the squamous, type I epithelium with a columnar epithelium. However, prominent areas of peribronchiolar fibrosis without columnar metaplasia have also been noted in the lungs of human smokers and of nonsmokers exposed to lung irritants (*18*).

In the present studies, hyperplasia of the type II epithelium appeared concurrently with changes in the interstitium. Alveolar bronchiolization was rather infrequent and appeared to occur well after inflammatory and fibrotic changes in the interstitium. In addition, the two types of larger lesions differed in other respects: Their locations were typically dissimilar, the type II lesions being mainly at the pleura. More importantly, the frequency of the lesions was related to the duration of tobacco smoke exposure. Increasing the time of exposure at the lower dose of tobacco smoke from 1 to 2 years led to approximately a tripling in the frequency of type II hyperplasias but to a sixfold increase in the frequency of peribronchiolar lesions. While exposure to 10 cigarettes/day for 1.5 years induced as many type II hyperplasias as the 2-year exposure to 7 cigarettes/day, it induced far fewer peribronchiolar lesions. Thus the peribronchiolar lesions were dependent on the duration of exposure and/or on the age of the exposed animals.

In summary, the rat inhalation model offers a prototype of human syndromes induced by tobacco smoke exposure. However, the exposure level required for induction of emphysematous changes also leads to high mortality. The ultrastructure of the lesions appears to implicate the inflammatory response in their pathogenesis. The least common lesion seen, fibrosis of the peribronchiolar alveoli, is temporally related to tumor incidence and can be considered a precursor lesion.

Noncytolytic Extraction of Murine Tumor-Specific Transplantation Antigens With the Nonionic Detergent Octyl-β-D-glucopyranoside[1,2,3]

Stephen J. LeGrue,[4,5,6] **Catherine M. Macek,**[5] *and* **Barry D. Kahan**[5,7]

ABSTRACT—The nonionic detergent octyl-β-D-glucopyranoside (C$_8$Glu) was used to extract immunogenic tumor-specific transplantation antigen (TSTA) from intact cells and purified plasma membranes of the 3-methylcholanthrene-induced fibrosarcoma MCA-F. Pretreatment of syngeneic C3H/HeJ mice with 100 μg of C$_8$Glu extracts induced specific immunoprotection such that mice resisted the outgrowth of MCA-F but not the antigenically distinct tumors MCA-D or MCA-2A. Incubation of intact cells with 7 m*M* (0.2%) C$_8$Glu for 30 minutes at 23°C was judged to be noncytolytic because extracted cells excluded trypan blue. Preparative isoelectric focusing partially purified the MCA-F-specific antigen from crude C$_8$Glu extracts into the pH 6.5–6.8 region of the gradient. Electrofocusing yielded 60% of the applied antigen activity and a fourfold to fivefold increase in specific activity. In addition, immunoprotective activity was obtained in 2% C$_8$Glu extracts of MCA-F plasma membranes, confirming the membrane localization of the MCA-F TSTA. Three properties of C$_8$Glu rendered it an attractive agent for the preparation of cell surface proteins: a nonionic character, large critical micellar concentration, and its capacity to extract antigens without complete membrane solubilization or cell disruption.—JNCI 1982; 69:131–136.

Carcinogen-induced murine neoplasms frequently express cell surface neoantigens that may serve as the focus of a host-tumor immune response (*1–4*). Vaccines containing whole-irradiated tumor cells (*5, 6*), subcellular fractions (*4, 7, 8*), or crude cellular extracts (*3, 7, 9–11*) are capable of inducing tumor-specific host immunity, such that mice can reject or resist the outgrowth of the same, but not other, syngeneic tumors. Intact 3-methylcholanthrene-induced fibrosarcoma (MCA-F) cells of C3H/HeJ mice release substantial TSTA activity during brief incubation in solutions containing 2.5% 1-butanol (*12*). The observation that butanol extraction was not cytotoxic led to an investigation of other agents that might release TSTA activity without attendant cytolysis. One such agent is the nonionic detergent C$_8$Glu.

Nonionic and weakly ionic detergents have been used to solubilize neoantigens from both virus- and carcinogen-induced tumors (*4, 10, 11, 13, 14*). However, the ionic characteristics of compounds such as sodium dodecyl sulfate, sodium cholate, and sodium deoxycholate limit their use in protocols that employ pIEF (*6, 12, 15*). In addition, the low CMC and large micellar dimensions of detergents such as Nonidet P40 and Triton X-100 (*16*) contribute to the difficulty in removal of these detergents from the isolated proteins. Mixed detergent-protein micelles restrict resolution in pIEF and the accurate assessment of molecular size by gel filtration.

These problems may be avoided by the use of the detergent C$_8$Glu, a molecule consisting of an eight-carbon alkyl chain attached to carbon atom 1 of D-glucose by an O-linked β-glycosidic bond. C$_8$Glu is completely nonionic and freely dialyzable to concentrations below the 25-m*M* CMC (*17, 18*). Since excess detergent can be removed from the extracted proteins, detergent-induced artifacts are minimized. Recently, C$_8$Glu has been used to solubilize the low-density lipoprotein receptor from human fibroblast membranes (*19*), the Ca^{2+} ATPase from sarcoplasmic reticulum (*20*), opsin from bovine retinal disks (*21*), a phosphoethanolamine transferase system from rat liver microsomes (*22*), and several enzyme activities from the membrane of *Streptococcus faecalis* (*18*). These workers report that C$_8$Glu concentrations ranging from 10 to 50 m*M* solubilize 25–100% of the protein from purified membranes. Maximum enzyme activity was usually observed in a narrow concentration range that was characteristic for each enzyme system.

C$_8$Glu extracted immunogenic TSTA activity from intact MCA-F cells. C$_8$Glu, like butanol, was not cytolytic at low concentrations. C$_8$Glu extracts of MCA-F cells possessed TSTA activity that was capable of inducing host resistance to challenge with viable MCA-F cells but not with the antigenically distinct MCA-D or MCA-2A tumors. Immunogenic activity was also observed in C$_8$Glu extracts of purified plasma membranes. The immunoprotective activity in C$_8$Glu extracts of MCA-F was partially purified by pIEF: Immunization with 23 μg of the pH 6.5–6.8 fraction significantly reduced subsequent homotypic tumor outgrowth. These results demonstrated that C$_8$Glu released substantial TSTA activity without cytolysis and that this detergent did not interfere with purification of the antigen by isoelectric focusing.

MATERIALS AND METHODS

Animals and tumors.—Fibrosarcomas MCA-F, MCA-D, and MCA-2A, induced with 3-methylcholanthrene (*9, 23*),

were maintained by serial sc transplantation in syngeneic C3H/HeJ female mice (The Jackson Laboratory, Bar Harbor, Maine). Tumors used for these studies were in transplant generations 4–7.

TSTA activity in crude extracts and plasma membranes was assessed according to the immunoprotection assay described in (*9*, *12*). Various doses of membrane or C_8Glu extract protein in Dulbecco's PBS (pH 7.4) were injected sc into groups of 10 syngeneic mice each. Hosts were challenged sc in the contralateral flank 10 days later with either 10^4 MCA-F, 10^4 MCA-2A, or 10^5 MCA-D cells (100 times the MTD). The mean tumor diameter of each group was calculated from individual tumor sizes, obtained as the average of two perpendicular measurements of tumor diameter with the use of a metric dial caliper. Significant differences in mean tumor diameters of control and antigen-treated groups were determined with the unpaired Student's *t*-test.

Specific activities of extracts and plasma membranes were determined with the immunoprotection assay. Specific activity was defined as the number of TSTA units per milligram of protein, where one TSTA unit is the milligram amount of protein necessary to reduce tumor growth by 33%.

Extraction of intact cells.—A single cell suspension of MCA-F was prepared by trypsin digestion of minced tumor tissue, as described in (*9*, *12*). The cells were washed twice and resuspended in Dulbecco's PBS (pH 7.4) containing the indicated concentrations of C_8Glu detergent (Calbiochem-Behring Corp., La Jolla, Calif.). Extraction in 7 m*M* C_8Glu for 30 minutes at 23°C maximized both the protein yield and viability of MCA-F cells. Following detergent extraction, cells were sedimented at 500×*g* for 10 minutes and washed three times prior to assessment of viability by trypan blue exclusion. The extract was dialyzed overnight against 100 vol of PBS, concentrated by dialysis against 50% sucrose in PBS, and redialyzed against PBS to remove the sucrose. After ultracentrifugation at 160,000×*g* (max) for 1 hour, the protein concentration of the supernatant fraction was determined with the use of the method of Bradford [(*24*); BioRad protein assay; Bio-Rad Laboratories, Richmond, Calif.] with ovalbumin as standard.

pIEF.—We achieved partial purification of the tumor antigen activity present in crude C_8Glu extracts by using pIEF (*6*, *12*, *15*). Crude C_8Glu extracts containing 40 mg protein in 1% glycine and 2% carrier ampholyte (pH 3.5–10) (LKB Instruments, Inc., Rockville, Md.) were electrofocused for 16 hours at 8 W, constant power, in a flatbed of Ultrodex (LKB Instruments, Inc.). After the gradient was sectioned into 31 fractions, the proteins were eluted into 10 ml of 0.3 *M* NaCl. The pH and protein concentration of each fraction were determined prior to assessment of immunoprotective activity.

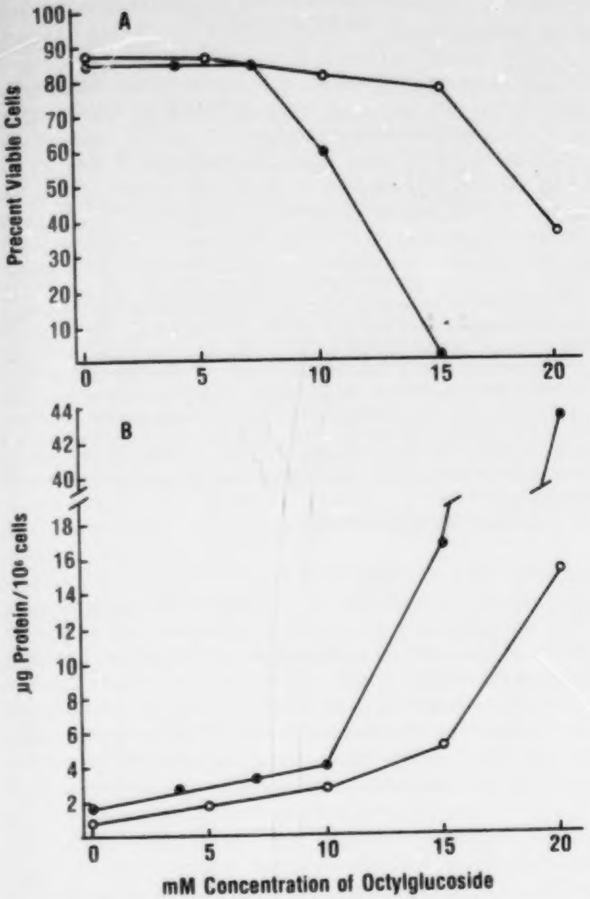
Extraction of plasma membranes.—Partially purified plasma membranes were prepared from MCA-F cells by a modification of the method described by Brunette and Till (*25*). All procedures were performed on ice or at 4°C. Tumors were harvested from 10–30 hosts and minced over a fine-wire screen. The minced tissue was washed thrice in PBS, resuspended in a lysis buffer of PBS containing 1 m*M* $CaCl_2$, 1 m*M* $MgCl_2$, and 2 m*M* phenylmethylsulfonyl fluoride. Cells were lysed with 40–50 strokes of a Potter-Elvehjem homogenizer fitted with a motor-driven Teflon pestle. The homogenates were centrifuged for 10 minutes at 1,000×*g* (max), and the supernatant fractions were stored in ice. The pellets were rehomogenized in lysis buffer and recentrifuged. The low-speed supernatants containing microsomal components were centrifuged at 40,000×*g* for 20 minutes. The resulting pellets were resuspended in a two-phase polymer suspension (*26*, *27*) and centrifuged in a swinging-bucket rotor for 10 minutes with a force of 20,000×*g* at the interface. The pellets were discarded, and the polymer phases and interfacial material were remixed and recentrifuged. The membrane pellicles were removed from the polymer interfaces by aspiration into silanized Pasteur pipettes, pooled, and washed in at least 10 vol of PBS before storage at −70°C.

Plasma membranes were extracted with C_8Glu by addition of 20 mg of membrane protein (0.5 ml) to 4.5 ml of 2.2% of C_8Glu in PBS. Following a 30-minute incubation at 23°C, the material was ultracentrifuged for 30 minutes at 104,000×*g* (max) in an Airfuge (Beckman Instruments, Inc., Palo Alto, Calif.) fitted with a batch rotor. The supernatant fraction was dialyzed overnight against 100 vol of PBS to remove C_8Glu and the ultracentrifugation was repeated to remove insoluble material.

RESULTS

Noncytotoxic Extraction With C_8Glu

Incubation of intact sarcoma cells in solutions containing low concentrations of C_8Glu released cell surface proteins without significantly affecting the ability of the extracted cells to exclude the supravital dye trypan blue. Both the protein yield and resistance of the cells to detergent-induced lysis were temperature-dependent (text-fig. 1). Extraction of 10^7 MCA-F cells suspended in 1 ml PBS containing less than 7.5 m*M* C_8Glu for 30 minutes at room temperature was not cytotoxic. When the extraction was performed at 4°C, cells survived C_8Glu concentrations up to 15 m*M*. The maximum protein yield obtained without loss of cellular viability was slightly greater at the lower temperature. However, at equivalent detergent concentrations, more surface protein was recovered with incubations at room temperature. The standard extraction condition for intact cells of 7 m*M* (0.2%) C_8Glu at 23°C for 30 minutes yielded 3–20 μg protein/10^6 cells, an amount equivalent to that obtained with 2.5% 1-butanol at 23°C for 5 minutes (*12*). Text-figure 1 also demonstrates that the rate of protein release into the supernatant fraction increased markedly when cellular viability fell below 50%. Incubation of cells at room temperature in 20 m*M* C_8Glu (text-fig. 1B) released 43 μg protein per 10^6 cells, which is about 10% of the total cellular protein (0.55 mg/10^6 cells) (*12*), while 10 m*M* C_8Glu extracts contained 5 μg, or 1% of the total cellular protein. These results indicate that the greater protein yield associated with extraction at high detergent concentration reflects the release of cytoplasmic proteins following C_8Glu-induced membrane lysis.



TEXT-FIGURE 1.—Effect of increasing C$_8$Glu concentration on cellular viability and protein yield. Intact MCA-F fibrosarcoma cells were incubated at 4°C (○) or 23°C (●) for 30 min in solutions containing C$_8$Glu. Viability was assessed by enumeration of cells excluding 0.01% trypan blue (A). Protein yield was determined following dialysis to remove excess detergent and ultracentrifugation (B).

Release of TSTA Activity From Intact Cells

Animals pretreated with 100 µg of a 7-m*M* C$_8$Glu extract prepared from intact MCA-F cells displayed a 45% reduction in the outgrowth of MCA-F tumor, when compared to the outgrowth in control mice (table 1). The specific activity of this extract (10 U/mg) is lower than that observed for butanol extracts (10–40 U/mg), but it is fivefold to tenfold greater than the specific activity of 3-*M* KCl extracts of MCA-F (*9*, *12*). To demonstrate that the tumor antigen activity released from cells by using 7 m*M* C$_8$Glu is specific for the tumor of origin, we immunized mice with 30 or 100 µg of crude C$_8$Glu extract from MCA-F cells and challenged them 10 days later with 100 times the MTD of MCA-F or 1 of 2 syngeneic but non-cross-reactive tumors, MCA-D or MCA-2A (table 2). Only animals pretreated with the homotypic extract displayed significant reduction in tumor outgrowth, when compared to control mice receiving PBS alone. Thus an immunogenic MCA-F-specific tumor antigen was among the polypeptides released from the surface of intact cells during incubation with low concentrations of C$_8$Glu.

TABLE 1.—*Immunoprotective activity of C$_8$Glu extracts prepared from intact MCA-F cells*[a]

Antigen	Dose, µg	Mean tumor diameter ± SE	Level of significance[b]
PBS	0	10.8±0.9	
C$_8$Glu extract	10	10.1±0.9	NS
	30	8.5±1.5	NS
	100	6.2±1.4	<0.02

[a] Extracts prepared by treatment of intact MCA-F cells with 7 m*M* C$_8$Glu were inoculated into groups of 10 syngeneic C3H mice each, which were challenged sc 10 days later with 10^4 MCA-F cells. Mean tumor diameters (mm) were determined 21 days post challenge.

[b] Determined by the two-tailed Student's *t*-test. NS=not significant.

Extraction of Plasma Membranes

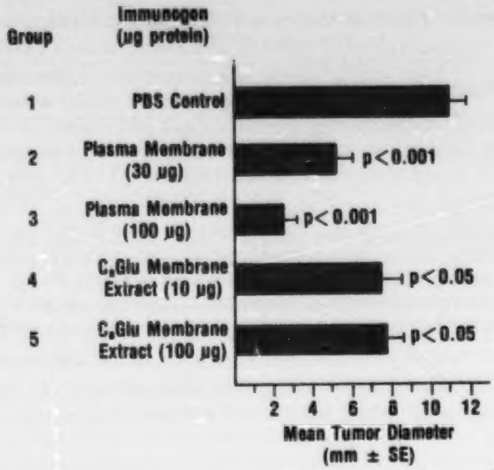
The noncytolytic release of TSTA activity from MCA-F cells by C$_8$Glu suggested that TSTA was associated with the exterior surface of the plasma membrane. Localization of the antigen in the plasmalemma was confirmed by the potent immunoprotective activity of the partially purified membrane fraction from MCA-F cells. Pretreatment with 30 or 100 µg of membrane-associated protein reduced tumor outgrowth by 48 and 77%, respectively (text-fig. 2). Extraction of 20 mg of MCA-F membrane protein in 5 ml of 2% C$_8$Glu (30 min, 23°C) released 1.5 mg (7.5%) of protein into the high-speed supernatant fraction. Pretreatment of hosts with 10 or 100 µg of the 2% C$_8$Glu extract significantly reduced ($P<0.05$) the mean MCA-F tumor diameter measured 21 days post challenge (text-fig. 2). The degree of tumor growth reduction induced with C$_8$Glu membrane extracts was significantly less than that observed with 100 µg of intact membrane protein as the immunogen ($P<0.05$). However, there was no significant difference between groups immunized with C$_8$Glu extracts and those receiving 30 µg of membrane protein.

TABLE 2.—*Specificity of TSTA activity noncytolytically extracted from MCA-F cells with the use of C$_8$Glu*[a]

Challenge tumor	Dose of MCA-F extract, µg	Mean tumor diameter±SE, mm
MCA-F	0	16.2±0.7
MCA-F	30	14.2±1.2
MCA-F	100	10.6±1.0[b]
MCA-2A	0	16.3±1.5
MCA-2A	30	16.6±2.6
MCA-2A	100	14.7±1.8
MCA-D	0	15.4±1.4
MCA-D	30	14.2±1.0
MCA-D	100	14.8±0.8

[a] Groups of C3H mice were immunized with the indicated doses of crude 7 m*M* C$_8$Glu extract prepared from intact MCA-F cells. Ten days later, mice were challenged sc with 10^4 MCA-F, 10^4 MCA-2A, or 10^5 MCA-D (100 times the MTD).

[b] Level of significance, $P<0.001$.

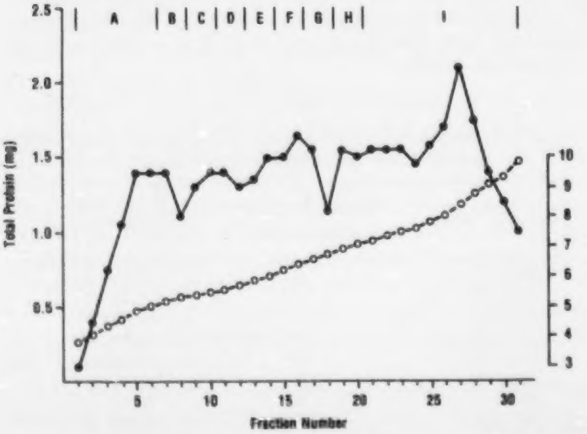


TEXT-FIGURE 2.—Immunoprotective activity of plasma membranes and C_8Glu extracts of membranes. Groups of 10 mice each were immunized with the indicated amounts of plasma membranes or 2% C_8Glu extract prepared from MCA-F plasma membranes. The mean MCA-F tumor diameters (mm ± SE) of control and experimental groups were determined 21 days post challenge. Statistically significant differences between antigen-treated mice and controls are shown. The significance of mean diameters between groups were as follows: group 2 vs. group 3, $P<0.05$; group 3 vs. group 4 or 5, $P<0.05$; all other comparisons were not significant.

Partial Purification of TSTA Activity by pIEF

The migration properties of MCA-F TSTA activity during electrofocusing are characteristic for the extraction technique used to obtain the antigen. Extracts prepared with 3 *M* KCl yielded immunoprotective activity at the pH 5.6–6.0 region of the gradient, while those prepared with 1-butanol electrofocused in the pH 6.4–6.5 region (*6, 12, 15, 28*). The protein distribution and pH gradient obtained following electrofocusing of 40 mg crude C_8Glu extract (text-fig. 3) demonstrated that the detergent did not adversely affect the generation of a linear pH gradient nor did C_8Glu appear to influence the migration of the proteins to their isoelectric points.

The fractions obtained by pIEF of MCA-F C_8Glu extracts were assessed for immunoprotective TSTA activity. A significant reduction in tumor outgrowth ($P<0.005$), relative to that in control mice receiving PBS, was observed only in



TEXT-FIGURE 3.—Distribution of C_8Glu extract protein following pIEF. Forty milligrams of a whole cell extract, prepared with the use of 7 m*M* C_8Glu, was electrofocused in a flatbed of Ultrodex containing 2% carrier ampholytes. After elution of the focused materials into 0.3 *M* NaCl, the pH and protein concentration of each fraction were determined. Fractions were pooled as indicated (A to I) for use in the immunoprotection assay (cf. table 3).

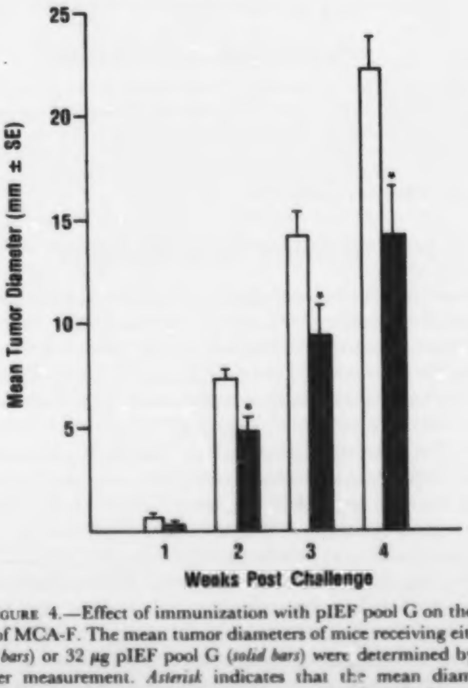
TABLE 3.—*Immunoprotective activity of pIEF fractions from a C_8Glu extract of MCA-F*[a]

Fraction pool	pH range	Immunizing dose, µg[b]	Mean tumor diameter ±SE, mm
	PBS-treated control	0	14.3±0.9
C	5.4–5.5	22	15.3±0.8
D	5.6–5.7	22	12.6±0.8
E	5.8–6.0	23	14.6±1.1
F	6.1–6.4	28	13.9±0.5
G	6.5–6.8	23	8.3±1.6[c]
H	6.9–7.1	25	15.7±0.4

[a] Groups of 10 mice each were immunized with the pIEF fractions and challenged 10 days later with 10^4 MCA-F; the mean tumor diameter was compared to that of PBS-treated controls 21 days post challenge.

[b] Immunizing dose was estimated to approximate the optimal dose for crude extract, with the formula $(mg_f)/(SA \times mg_t)$, where mg_f is the amount of protein in a particular fraction, *SA* is the specific activity of the crude extract (TSTA unit/mg), and mg_t is the total amount of protein recovered from all fractions. This formula assumes that activity is not preferentially lost or retained and that all the activity is present in a single fraction.

[c] Level of significance, $P<0.005$.



TEXT-FIGURE 4.—Effect of immunization with pIEF pool G on the growth rate of MCA-F. The mean tumor diameters of mice receiving either PBS (*open bars*) or 32 µg pIEF pool G (*solid bars*) were determined by weekly caliper measurement. *Asterisk* indicates that the mean diameters of tumors in the fraction-treated group were significantly less ($P<0.02$) than those in saline-treated controls.

mice pretreated with 23 μg of the pH 6.5–6.8 portion of the gradient (text-fig. 3, fraction pool G). Immunization with equivalent doses of other pIEF fractions had no effect on subsequent tumor outgrowth (table 3). The reduction in mean tumor diameter in mice receiving the pH 6.5–6.8 fraction was statistically significant ($P<0.02$ or greater) at 14, 21, and 28 days post challenge (text-fig. 4). In addition, the rate of tumor outgrowth in antigen-treated mice (0.67 mm/day, $r=0.999$) was significantly slower ($P<0.01$) than the rate of growth in control mice (1.01 mm/day, $r=0.999$). This degree of tumor growth retardation was comparable to that following pretreatment with either 100 μg of the crude, unfractionated C_8Glu extract or 30–100 μg of the crude butanol extract. Thus electrofocusing produced a fourfold to fivefold increase in specific antigen activity, relative to that in the crude C_8Glu preparation, with greater than 95% recovery of applied protein. The pH 6.5–6.8 fraction (pool G) contained 6.6% of the starting crude extract protein and 60% of the applied antigenic activity, calculated on the basis of the ability of a given milligram amount of crude or partially purified C_8Glu extract to effect a 33% reduction in mean tumor diameter.

DISCUSSION

Treatment of either intact cells or plasma membrane-enriched fractions from the 3-methylcholanthrene-induced fibrosarcoma MCA-F with solutions containing C_8Glu released significant immunoprotective TSTA activity. C_8Glu, a member of the alkyglucoside detergents described by Baron and Thompson (*18*), consists of an eight-carbon alkyl group attached to carbon atom 1 of D-glucose via an *O*-linked β-glycosidic bond. Thus C_8Glu is completely nonionic except under the most extreme alkaline conditions. The relatively high 25 m*M* CMC reported for C_8Glu (*17*) allows complete removal of excess detergent by simple dialysis (*18*). This is in sharp contrast to the properties of other detergents commonly used for the solubilization of membrane proteins, which have CMC's in the range of 0.1–1.0 m*M* (*16*). Detergents with low CMC's are intransigent to removal by dialysis or gel filtration (*18*, *29*) because the monomer concentration is small compared to the total detergent concentration.

The ability of C_8Glu to liberate TSTA activity from the surface of intact cells without reducing cellular viability is similar to the noncytolytic butanol extraction procedure reported previously (*12*). However, extraction with C_8Glu differs from 1-butanol extraction in that 1) the cells may be incubated in low concentrations of C_8Glu for long periods of time at either 4°C or 23°C without loss of viability, 2) the protein yield and cellular viability are less dependent on pH and ionic strength in C_8Glu extraction, and 3) the specific activities of crude C_8Glu extracts are lower than those of crude 1-butanol extracts. The observation that both C_8Glu and 1-butanol release tumor antigen activity without attendant cytolysis suggests that the antigens are more weakly associated with the plasma membrane than are integral proteins such as histocompatibility antigens, which frequently require complete membrane solubilization to effect their release (*16*, *30*).

The relatively mild conditions required to release TSTA activity from intact cells, together with the potent immunoprotective activity of plasma membranes, suggested that tumor antigen might also be obtained by treatment of purified tumor cell membranes with C_8Glu. Extraction of intact MCA-F cells with 10 m*M* C_8Glu released 5–10 μg protein/10^6 cells, an amount equivalent to that obtained (4–6 μg) by extraction of membranes prepared from 10^6 cells with the same concentration of detergent. Thus low concentrations of C_8Glu release proteins from both sources with equal efficacy. Complete solubilization of the isolated membranes was achieved by overnight incubation in 2% (68 m*M*) C_8Glu (data not shown), but only 60% of the protein remained in solution following dialysis and ultracentrifugation. Although the 2% detergent extract displayed significant immunoprotective activity, its specific activity was less than that of the intact plasma membranes. Thus pretreatment with 10 or 100 μg of extracted membrane protein reduced mean tumor size by 33%, while immunization with 100 μg of partially purified membranes effected a 77% reduction in tumor outgrowth. The greater ability of membranes, relative to membrane extracts, to elicit immunoprotective activity may be due to 1) the enhanced immunogenicity of particulate over soluble antigens (*4*, *7*), 2) loss of TSTA during the processing of the crude extract, or 3) the masking or denaturation of immunogenic sites on the solubilized antigen resulting from the binding of detergent molecules (*20*, *22*). Determination of an optimal C_8Glu concentration for the extraction of these antigens may reduce the disparity between the specific activities of the in situ and the extracted TSTA.

The biologically active TSTA moiety extracted from intact MCA-F cells with C_8Glu was partially purified by pIEF at the pH 6.5–6.8 region of the gradient. The apparent isoelectric pH of the C_8Glu-extracted antigen is slightly more basic than that reported for antigen released with the use of 1-butanol (*12*), and it is one full pH unit higher than the isoelectric pH of the 3-*M* KCl-extracted moiety (*6*, *15*). The significantly greater isoelectric pH of the tumor antigens extracted by noncytolytic techniques, compared to TSTA released after exposure to 3 *M* KCl, may reflect differences in extraction mechanisms. The slightly different migration of 1-butanol- and C_8Glu-extracted antigens in pIEF might result from minor differences in the conformations of the antigens following extraction due to the association of residual extractant. However, if C_8Glu remains bound to the extracted antigen, it does not appear to affect the focusing of antigen into a discrete region of the pIEF gradient; 60% of the applied activity was recovered in 7% of the applied protein, resulting in a fourfold to fivefold increase in specific tumor antigen activity. Conversely, when extracts prepared with the nonionic detergent Nonidet P40 were electrofocused, the presence of mixed protein–detergent micelles resulted in a smearing of protein across the entire pH gradient, with no detectable TSTA activity in any fraction (data not shown).

Heretofore, the preparation of soluble tumor antigens suitable for immunoprotection assays and for biochemical characterization has relied on treatment of whole cells or subcellular fractions with detergents or hypertonic salt solutions. These techniques have yielded materials that are active but which often contain numerous extraneous components, complicating isolation and characterization of the extracted antigens. Noncytolytic extraction techniques, such as 1-butanol and C_8Glu extraction, yield biologically active membrane proteins unencumbered by cytoplasmic components or intransigent residual detergents. Thus noncytolytic extraction may facilitate analysis of certain plasma membrane antigens by providing preparations containing only membrane-associated molecules in a form amenable to fractionation by classical biochemical techniques.

Use of Young Nude Mice for Selection of Subpopulations of Cells With Increased Metastatic Potential From Nonsyngeneic Neoplasms[1, 2, 3, 4]

Vincent A. Pollack[5, 6] *and* **Isaiah J. Fidler**[5, 7]

ABSTRACT—The purpose of these studies was to investigate whether young (3-wk-old) nude mice, which lack functional T-lymphocytes and demonstrate low natural killer cell activity, could serve as in vivo models for the selection of metastatic subpopulations of cells from heterogeneous allogeneic melanomas. Three-week-old BALB/cAnN or N:NIH(S) nude mice received iv injections of single cells harvested from either the B16 or K-1735 melanoma. Individual pulmonary metastases were harvested 4 weeks later and implanted sc into nude mice to expand the population. Cells from each of these metastases colonized in the lungs of 3-week-old nude mice and 6-week-old normal syngeneic mice with significantly higher efficiency than did cells from the parent tumors. It was concluded that, in addition to being a useful in vivo model for ascertaining the metastatic potential of neoplasms, the healthy young nude mouse could be used for selecting and maintaining tumor cell variants of high metastatic potential from heterogeneous allogeneic tumors.—JNCI 1982; 69:137–141.

Cancer metastasis represents a complex series of tumor cell-host interactions that result in proliferation of tumor cells at organs distant from the primary neoplasm. Throughout this process, tumor cells are exposed to various host antitumor defenses, and the rules of "survival of the fittest" apply. As a result, metastasis is currently viewed as a process selective for preexistent metastatic cells that probably constitute a minor subpopulation of the primary tumor (*1–7*).

Recent evidence indicates that developing primary neoplasms may be comprised of subpopulations of cells with widely disparate phenotypes, a few subsets of which may confer selective survival advantages (*7, 8*). These include antigenic and immunogenic properties, growth rates, karyotypes, and cell surface receptors, among others (*2, 7, 8, 9–12*). Furthermore, malignant neoplasms are populated by cells of unequal invasive and metastatic capabilities (*13–15*). The heterogeneity of tumors with respect to response to cytotoxic drugs has profound implications for the way in which potential agents are selected for the treatment of metastases. Both human and animal tumors may contain subpopulations of cells with different sensitivity to cytotoxic agents (*7, 10, 12, 16–19*). Moreover, differences in response to drug treatment have been reported between primary neoplasms and their metastases (*16, 19*) and even among the metastases themselves (*19*). Taken together, these factors pose major problems to oncologists whose primary goal in cancer treatment is to eradicate metastases. Since the clinically important subpopulations of highly metastatic and/or chemotherapy-resistant tumor cells may represent minor subsets of the primary tumor, the sampling of primary tumors becomes problematic and such samples may not be representative of cells populating distant micrometastases (*7*).

Several methods have been described to isolate subpopulations of cells with increased metastatic potential from a heterogeneous malignant neoplasm. Perhaps the most widely used procedure is the one we initially described for the B16 melanoma. This procedure involves the isolation and propagation of variant lines from metastatic foci (*1*). In such diverse murine tumor systems as melanoma, fibrosarcoma, 3-methylcholanthrene-induced sarcoma, Lewis lung carcinoma, lymphoma, and lymphosarcoma, variants with different metastatic potential have been selected (*7, 9*). Essential to the success of such a procedure is the availability of normal syngeneic recipients for both the selection and the testing of the metastatic cells. Clearly, this is not a feature of autochthonous human tumors. The demonstration that 3-week-old nude mice, in which the NK cell system is not yet activated (*20, 21*), can be used for quantitation of the metastatic potential of neoplasms (*20, 22*) has encouraged us to use the athymic mouse for the selection of metastatic subpopulations from the allogeneic heterogeneous B16 melanoma and K-1735 melanoma parent tumor populations.

MATERIALS AND METHODS

Animals.—Five- to 6-week-old male $B6C3F_1$ mice (C57BL/6 × C3H/HeN mammary tumor virus negative) and 3-week-old male athymic (*nu/nu*) nude mice of N:NIH(S) and BALB/cAnN backgrounds were used. All mice were specific pathogen-free and were obtained from the Animal Production Area of the NCI-Frederick Cancer Research Facility.

Tumors.—The origin and maintenance of the spontaneous murine B16 melanoma, syngeneic to C57BL/6 mice, have

been described previously (*1–3*). The melanoma's invasive and metastatic properties have been attributed to minor subpopulations of metastatic cells that preexist within the parent tumor (*13*). The induction and properties of the K-1735 melanoma, syngeneic to C3H/HeN mice, have been previously described (*23*). The in vitro production and characterization of many cloned cell lines, as well as the metastatic potentials of each, were also recently reported (*5, 14*). All tumor lines were maintained in vitro in complete Eagle's minimal essential medium that contained 5% fetal bovine serum and that was supplemented with glutamine, nonessential amino acids, and vitamins. Cultures were maintained at 37°C in a humidified atmosphere containing 5% CO_2. The tumor lines were free of mycoplasma and the following murine viruses: reovirus type 3, pneumonia virus of mice, K-virus, Theiler's virus, Sendai virus, ectromelia virus, and lactate dehydrogenase virus.

For in vivo studies, we harvested the tumor cells from cultures in their exponential growth phase by overlaying the cells with a thin layer of 0.25% trypsin–0.02% EDTA for 1 minute. The cells were washed and resuspended in HBSS. Tumor cell viability was assessed by trypan blue exclusion, and only single cell suspensions of greater than 95% viability were used in the study (*3*). For in vivo experiments involving sc passaged tumors (1–2 cm), single cell suspensions were prepared by enzymatic dissociation with the use of HBSS containing 0.14% collagenase type I, 0.03% DNase, and 50 µg gentamicin/ml). Enzymes were purchased from Sigma Chemical Co., St. Louis, Mo.

Selection of metastatic tumor cell variants in syngeneic mice.—In the first set of experiments, we isolated metastatic variants from the B16 melanoma and the K-1735 melanoma by recovering spontaneous lung metastases produced from a subcutaneous parent tumor implanted into the hind footpad of mice (*3*). Individual spontaneous metastases (designated as SMet-1, SMet-2, and so on) were removed aseptically and transplanted by trocar into syngeneic mice to expand their population before their metastatic potential was tested in both syngeneic and allogeneic nude mice.

Selection of metastatic tumor cell variants in allogeneic nude mice.—BALB/cAnN nude mice, 3 weeks old, received iv injections of 5×10^4 viable cells of either the B16 melanoma or the K-1735 melanoma. About 3–4 weeks later, the mice were killed, and solitary metastases harvested from different mice were transplanted by trocar implantation into the subcutis of nude mice (1 metastasis/mouse). The metastases were designated as NuMet-1, NuMet-2 and so on. After sc growth, both parent tumors (B16 and K-1735) and the various metastases were tested for their metastatic potential in both syngeneic mice and allogeneic nude mice. In all experiments, we took great care to prevent cross-contamination of tumor samples.

Testing of the metastatic potential of cells from the parent tumor and from their spontaneous metastases.—Parent tumors and individual metastases (selected either in syngeneic mice or in young nude mice) were transplanted sc into mice to expand their populations. Suspensions of single viable tumor cells were prepared from the individual subcutaneous tumor mass by a modification of the enzymatic dissociation technique described by Peters et al. (*24*). Individual subcutaneous tumors (1–2 cm) were aseptically excised, cut into 1-mm pieces, and rinsed several times with HBSS. The fragments were placed into a sterile vial containing a small magnetic stirring bar and two-thirds capacity (≈10 ml) of sterile dissociation medium (0.14% collagenase type I, 0.03% DNase, and 50 µg gentamicin/ml of HBSS). Vials were taped to the platform of a magnetic stirring device and gently agitated (without frothing) for 15–25 minutes at room temperature. All suspensions were filtered through a sterile silkscreen and centrifuged, and the cells were resuspended in HBSS. Cell viability was determined by the trypan blue dye exclusion test. After enumeration, the suspension was diluted to the desired cell concentration.

We tested the metastatic potential of tumor lines by monitoring the induction of experimental pulmonary metastases as previously described (*3–5, 13*). Portions of cell suspensions (0.2 ml) were injected into the lateral tail vein of unanesthetized syngeneic $B6C3F_1$ mice or 3-week-old nude mice after disinfection of the site with 70% ethanol. After 21 days, the mice were killed and their lungs were placed in Bouin's fluid; peripheral lung colonies were counted with the use of a dissecting microscope. Results are expressed as the median and range of lung tumor counts. Differences between the groups were analyzed with the Mann-Whitney *U*-test (*13*).

RESULTS

In the first set of experiments, we examined whether tumor cells populating spontaneous metastases produced from a parent tumor growing in syngeneic mice had greater metastatic potential than cells populating the parent tumor. Moreover, we also confirmed our earlier data (*20, 21, 25*) that young (3-wk-old) nude mice are suitable for studies designed to distinguish cells with low or high metastatic potential. The data for the B16 system are summarized in table 1 and for the K-1735 system in table 2. Essentially, the data demonstrate that in both syngeneic mice and allogeneic nude mice, cells from spontaneous metastases

TABLE 1.—*Metastatic potential of cells from the parent B16 melanoma and spontaneous metastases (isolated in syngeneic mice) determined by measurement of experimental pulmonary metastasis in syngeneic ($B6C3F_1$) or allogeneic [N:NIH(S)] nude mice*

Source of cells	Median No. (range) of pulmonary tumor colonies[a]	
	Syngeneic mice, 6 wk old[b]	Allogeneic nude mice, 3 wk old[c]
$B16–F_1$ (parent)	39 (18–90)	2 (0–7)
B16 SMet-1	>400 (all >300)	>400 (all >400)
B16 SMet-2	236 (202–424)	198 (121–>300)
B16 SMet-3	198 (112–335)	126 (45–251)
B16 SMet-4	>300 (263–>300)	230 (103–400)
B16 SMet-5	197 (135–284)	254 (25–342)

[a] The median No. of tumor colonies differed significantly from that produced by cells of the parent tumor, $P<0.001$.

[b] Groups of 10 mice received iv inoculations of 25,000 viable cells/mouse in 0.2 ml of HBSS. Mice were killed 3 wk later, and their lung tumor colonies were counted under a dissecting microscope.

[c] Groups of 10 mice received iv inoculations of 12,500 viable cells/mouse and were killed 4 wk later.

produced significantly more experimental lung tumor nodules than cells isolated from the unselected parent population ($P<0.005$). It is important to note that, for the studies in nude mice, we used fewer tumor cells in the inoculum than we used for studies in syngeneic animals because of the increased sensitivity of young nude mice to the formation of experimental metastases (*21*). Nonetheless, cells of the metastatic variants were capable of greater lung colonization than cells from the unselected parent tumors. Despite the lower cell content of the inoculum, the metastatic variants SMet-2 and SMet-4 of the B16 melanoma produced extensive extrapulmonary (intrapleural) metastases. Variants SMet-1 and SMet-5 were particularly virulent, resulting in early deaths because of extensive pulmonary and extrapulmonary metastases. Collectively, these data confirm that young nude mice can be used to distinguish cells of low and high metastatic potential (*21*).

In the second set of experiments, we attempted to determine whether the iv injection of tumor cells into nude mice is selective for metastatic variants of allogeneic (B16 and K-1735) melanomas. Groups of 10 nude mice each received iv injections of serial twofold dilutions of either B16—F_1 parent melanoma cells or K-1735 parent melanoma cells. Four weeks later, solitary lung tumor colonies were harvested from the peripheral lung tissue of mice with well-isolated nodules (10–20 nodules/lung). Each nodule was transplanted by trocar into a single young nude mouse. In this manner, seven B16 isolates (designated B16 NuMet-1 to NuMet-7) were tested for their metastatic potential as compared to that of the unselected parent population (table 3). For these experiments mice received iv injections of 10^4 viable cells. Tested in nude mice, cells from 6 of 7 metastases were significantly more metastatic than cells of the parent B16 tumor ($P<0.001$). This enhanced metastatic potential of the cells was expressed not only in young nude mice: Similar data were obtained when the metastatic potential of parent B16 and metastases (isolated in nude mice) was tested in syngeneic mice. Cells from 5 of 7 metastases were significantly more metastatic than cells isolated from the parent tumor ($P<0.001$).

TABLE 2.—*Metastatic potential of cells from parent K-1735 melanoma and spontaneous metastases (isolated in syngeneic mice) determined by measurement of experimental pulmonary metastasis in syngeneic (C3H/HeN) or allogeneic [N:NIH(S)] nude mice*

Source of cells	Median No. (range) of pulmonary tumor colonies[a]	
	Syngeneic mice, 6 wk old[b]	Allogeneic nude mice, 3 wk old[c]
K-1735 (parent)	43 (6–165)	69 (21–331)
K-1735 SMet-1	360 (11–410)	205 (61–251)
K-1735 SMet-2	148 (9–365)	127 (44–223)

[a] Groups of 10 mice received iv inoculations of 25,000 viable cells. Mice were killed 4 wk later, and their lung tumor colonies counted with a dissecting microscope.

[b] Groups of 10 mice received iv inoculations of 50,000 viable cells.

[c] The median No. of lung tumor colonies differed significantly from all other groups, $P<0.001$.

In a similar manner, putatively metastatic variants of the K-1735 melanoma were selected in the nude mouse and later tested for their metastatic potential in both adult syngeneic mice and 3-week-old BALB/cAnN nude mice (table 4). Cells of the parent K-1735 tumor produced a median of 19 lung tumor colonies (range, 3–56) in nude mice and a median of 44 lung tumor colonies (range, 17–148) in syngeneic mice. In contrast, the lines selected in the nude mice were uniformly highly metastatic and produced hundreds of peripheral lung tumor nodules. In each case, results of tests in the syngeneic mice paralleled those in nude mice. The results also indicate that sc growth did not affect the metastatic potential of either the parent or the metastatic variants. In subsequent experiments (data not shown), we have found that even several successive sc transplantations do not influence the metastatic potential of selected or unselected tumor populations.

DISCUSSION

Recent data from our laboratory have demonstrated that specific pathogen-free, 3-week-old nude mice, which lack functional T-lymphocytes (*26*) and which demonstrate low NK cell activity, could serve as in vivo models to ascertain the metastatic potential of allogeneic and xenogeneic tumors (*20, 21, 25*). Our present data confirm these observations and show, in addition, that young nude mice can be used to select from within a heterogeneous allogeneic tumor those subpopulations of cells that possess increased metastatic potential, in both nude mice and their original syngeneic hosts.

For the present studies, we used the B16 melanoma (*13*) and K-1735 melanoma (*14*) previously shown to be heterogeneous with regard to various biologic properties that include invasion and metastasis. Cells isolated from parent tumors or their spontaneous metastases were introduced into the circulation of either syngeneic mice or allogeneic nude mice. In both hosts, cells isolated from spontaneous metastases that had developed in the autochthonous (syngeneic) host produced significantly more experimental metastases ($P<0.005$) than cells isolated from the parent tumors. These data, therefore, demonstrate that the outcome of experimental metastasis in the young nude mice paralleled the pattern observed when parent and/or metastatic cells were injected iv into syngeneic $B6C3F_1$ recipients (tables 1, 2). The metastatic potential of tumor cells was ascertained by determining the production of "experimental" metastases after the introduction of cells into the circulation. This procedure eliminates the need for initial detachment of cells from the primary neoplasm and invasion into blood vessels. However, all the subsequent steps in the metastatic process must occur for the iv injected cells to establish a metastasis. Elimination of the initial steps in the process introduces the risk that noninvasive tumor cells might form metasases when injected iv but be unable to metastasize from a tumor growing sc or im. This question has been addressed by Kripke et al. (*15*) who studied the metastatic behavior of 21 clones of the UV-2237 fibrosarcoma syngeneic to the C3H mouse by using three different assays: 1) formation of experimental metastases after iv injection, 2) formation of experimental metastases after sc implantation, and 3) survival time of animals after receiving iv injections. When the clones were ranked in order of increasing metastatic behavior, a strong correlation was found among all three tests for 20 of 21 clones. Thus the production of experimental metastases is a valid assay for determining the potential of cells for spontaneous metastasis. Similar data have also been reported for the B16 melanoma system (*27*) and the K-1735 melanoma system (*14*).

The existence in heterogeneous neoplasms of minor but specialized subpopulations of cells that can give rise to metastases has profound implications for testing agents designed to treat disseminated disease (*7, 10, 11*). Differences in the response of primary and metastatic lesions (*2, 10, 16, 17*) or of various metastases (*19*) to therapeutic agents are well documented in clinical practice. Procedures that use unselected heterogeneous tumors to select effective agents for treatment of metastases may be unable to identify a beneficial response against the minor but fatal subpopulation of metastatic cells that exists in the neoplasm (*7*). Future assays to identify potential agents for treatment of metastases should ideally utilize tumor cell populations with defined metastatic capabilities (*9*).

Our studies demonstrate that young nude mice can be used for selection of populations of tumor cells with increased metastatic potential as tested in their original hosts (tables 3, 4). The ability of the athymic mouse to discriminate metastatic from nonmetastatic cells functions across major histocompatibility barriers, demonstrated by the fact that the N:NIH(S) and BALB/cAnN nude mice were allogeneic to the C57BL/6 and C3H/HeN mice from which the tumors were derived. We stress that the use of specific pathogen-free nude mice is mandatory to the success of the procedures we outlined. Nude mice infected with murine hepatitis virus or other pathogenic microorganisms exhibit increased activity of their NK system (*28*) and are resistant to the production of metastases (*20, 21*) or even growth of tumor allografts and/or xenografts at a subcutaneous site (*29–31*).

Taken together, our results suggest that the athymic nude mouse may be used for selection, isolation, and maintenance of tumor cell variants of high metastatic potential. They further suggest that since nude mice accept tissue grafts from a variety of sources (*32, 33*), they could be used for the identification and selection of metastatic cell variants across a greater (i.e., xenogeneic) histocompatibility barrier.

Photochemical Toxicity: Toxic, Allergic, and Carcinogenic Aspects With Emphasis on Predicting Effects in Humans—an Introduction[1]

F. Alan Andersen, *Ph.D.*[2]

In April 1975, the then Associate Commissioner for Science in the FDA, Dr. Lloyd Tepper, in a memorandum to all FDA Bureau Directors, included the following:

> It has been something of a surprise to note that light is implicated, to a greater or lesser degree, in the activities of each Bureau: cosmetics and photosensitization in the Bureau of Foods, chemophototherapy and photodermatitis in the Bureau of Drugs, phototherapy and various light products for the Bureau of Radiological Health and the Bureau of Medical Devices, microbiological control for the Bureau of Biologics, and laser analytical procedures used in the Bureau of Veterinary Medicine.

The interest is even broader now as a result of efforts to communicate the nature of the problem as it affects each Agency component. With this symposium, that communication is expanded to include affected industry and the medical, scientific, and consumer communities.

In a way, we are all coming in late. At the turn of the century, it was demonstrated that an acridine dye could act synergistically with light to produce oxygen-dependent killing of paramecia (*1*). In the 80 years that have passed significant progress has been made in understanding the molecular basis for that early finding. Such basic research, however, has infrequently touched upon the implications for humans of sensitivity induced by a light-activated chemical. Moreover, this research has generated more questions.

For example, on the one hand, is light the great uncontrolled variable responsible for ambiguous chemical toxicity data, which FDA often faces in approval decisions? Could light, incident on individuals exposed to a chemical, on the other hand, be responsible for toxic reactions not uncovered in clinical or preclinical trials? Recent work suggests that the answer to both questions is yes (*2*).

Let us explore briefly just what is included in this area about which we are going to spend 2 days discussing. Chemical photosensitivity is a general term commonly used to describe abnormal or adverse light-induced chemical reactions in humans. Classically, this includes toxic and allergic responses to light plus chemicals. For purposes of this discussion, though, the general term is going to be expanded into three categories: chemical phototoxicity, chemical photoallergy, and (we are going to add) chemical photocarcinogenicity.

Chemical phototoxicity in humans is similar to many primary responses to irritants. Commonly, the skin response might mimic sunburn. Chemical photoallergy may be best described as getting a case of hives. Chemical photocarcinogenicity was suspected as early as 1937 for light-exposed mice subjected to sc injections of eosin or hematoporphyrin (*3*). More recently, an increased risk of nonmelanoma skin cancer has been found for patients treated with derivatives of the drug psoralen and UVA radiation (UV radiation between 320 and 380 nm) for severe psoriasis (*4*).

These responses in humans are serious consequences of simultaneous exposure to light and chemicals. It is important to emphasize that the responses might not be limited to body surfaces since circulating blood is also exposed to light. Because people are frequently exposed to light and because chemicals can be injected, ingested, or rubbed on, instances of simultaneous exposure are beyond calculation. Many chemicals cause photosensitivity, for example, because of their interaction with UV radiation. UV radiation can come from the sun or from a number of man-made sources, including high-intensity mercury vapor lamps, xenon lamps, medical phototherapy lamps, sunlamps, and even fluorescent lamps (*5, 6*). Because light sources can vary so in their intensity and their spectral quality, an important part of this symposium will be to introduce you to the topic of what is emitted from lights and how to measure it. We do not want you going back to your laboratories and checking out your lights with a light meter designed for your camera.

The number of chemical agents will also affect the magnitude of concern. A list, published in 1963, of photosensitizing chemicals contains at least 43 chemical agents, ranging from a buckwheat derivative to coal tars to various medications (*7*). A similar list, published in 1974 by essentially the same authors, had grown to 68 items, including dyes, essential oils, and additional medications (*8*). When we note that certain of these dyes are used in procedures such as retinal angiography (*9*) and that the earlier list already contained at least one agent used as an optical brightener in laundry detergent (*7*), the concern is further magnified.

Natural photosensitizers (endogenous biochemical species that interact with light) have also been described (*3*), and we will hear more about these during the symposium.

As a final piece of information relating to the magnitude of the problem from the chemical side, let me just note that one compilation includes 400 compounds that could act as sensitizers by interacting with molecular oxygen (*10*). This question of interaction is not limited to two dissimilar agents such as light and chemicals. A recent National Research Council report (*11*) noted that people normally are exposed to combinations of chemicals rather than to a single chemical, and, stating the obvious perhaps, it went on to note that "basic information on the effects of mixtures and

human body's reaction to them is lacking." It recommended further research on this difficult and complex problem and observed that, until a data base is available, the only practical approach is to test the specific mixtures of compounds for which information is needed.

To some extent, we face the same problem. Our information comes from both clinical and preclinical tests used for determining the potential of a given chemical to be a photosensitizer. Clinically, a photo-patch test is often used. Preclinical testing, however, can be done with the use of either animals or in vitro test systems. Currently, the guinea pig is used in most animal tests. As in the clinical studies, erythema is often the end point, and testing can be complete in a couple of weeks. In yet another system, the hairless mouse has been used to test for tumorigenesis by use of a procedure that can require 100 weeks to perform. In vitro tests include DNA cross-linking and induction of oncogenic virus. The assay for DNA cross-linking has also been used to detect chemical photosensitization in hairless mouse skin (*12*). Mammalian erythrocyte hemolysis is the classic assay for membrane chemical photosensitization, although, recently, effects on excitable cell membranes have shown themselves to be another quantifiable assay (*13*).

We will hear more about recent advances in all of these areas as the symposium progresses. In fact, that is what it is all about. As regulators, the FDA will have to decide how current test systems should be incorporated in the testing protocols for drugs and food additives. As part of the affected group, be it manufacturer, practitioner, scientist, or consumer, you need to participate. Such decisions will also influence the kind of test data the Agency will require to demonstrate that a cosmetic ingredient is harmful under normal conditions of use. So this symposium covers all areas of FDA, from foods to drugs to cosmetics, and includes radiation as a modifier in each of them.

In all of this future action, the evaluation of light-induced chemical carcinogenesis remains elusive. Current animal tests may take too long to serve as a screening tool. A test such as in vitro DNA cross-linking may not be sufficiently predictive of chemical photocarcinogenesis to be of use. We need a test system that can be used as a screen to determine whether a chemical should be tested in animal systems or not, and we need such a system soon.

Optical Radiation Measurements: Instrumentation and Sources of Error[1, 2]

Robert J. Landry[3] *and* **F. Alan Andersen**[4]

ABSTRACT—Accurate measurement of optical radiation is required when sources of this radiation are used in biological research. The most difficult measurements of broadband noncoherent optical radiations usually must be performed by a highly trained specialist using sophisticated, complex, and expensive instruments. Presentation of the results of such measurement requires correct use of quantities and units with which many biological researchers are unfamiliar. The measurement process, physical quantities and units, measurement systems and instruments, and sources of error and uncertainties associated with optical radiation measurements are reviewed.—JNCI 1982; 69:155–161.

Accurate measurements of optical radiation are required for the proper description of radiation sources used in biological research. Measurements are also required for the design of products for various applications such as PUVA therapy devices for the treatment of psoriasis, photocopiers, and photopolymerization processes. Here, knowledge of the efficacy of the optical radiation is of paramount importance. The evaluation of potential hazards from optical radiation that may be associated with the various products such as welding arcs and high-intensity discharge lamps also requires accurate measurements. Unfortunately, accurate measurement of broadband noncoherent optical radiation is not trivial. It is best performed by a highly trained specialist and it requires the use of sophisticated, complex, and expensive instrumentation.

The measurement process is further complicated by the fact that the optical radiation quantity to be determined depends on the particular application. For example, the optical radiation quantity to be determined for accurate evaluation of the potential hazards to the retina of the eye is different from that quantity required for evaluation of the potential hazards to the skin and cornea of the eye. In addition, the presentation of the results of measurement processes requires correct use of quantities and units with which many biological researchers are unfamiliar.

This paper will outline important considerations in optical radiation measurements. The first section covers radiometric quantities and units, measurement systems, and instrumentation. Sources of error and uncertainties associated with optical radiation measurements are discussed in the second section.

RADIOMETRIC QUANTITIES AND UNITS, MEASUREMENT SYSTEMS, AND INSTRUMENTATION

Quantities and Units

The essential radiometric quantities and units of interest for the applications referred to in the introduction are listed and defined in table 1. For almost 10 years, work has progressed toward development of an approach to quantities and units that would be applicable to all radiation (*1–4*). Such a unified system requires compromise, of course, and certain quantities in table 1 could be presented differently (*4*). Regardless of the exact nature of the quantities and units, it is critical that nomenclature such as that in table 1 be used to express the results of optical radiation measurements.

Another aspect of nomenclature that warrants brief comment is the naming of various regions of the spectrum. To different people, the names can mean various things. For example, the separation of the visible from the UV portion of the electromagnetic spectrum is at 380×10^{-9} m for some and at 400×10^{-9} m for others; the lower limit of "UVA" may be at 315×10^{-9} m or 320×10^{-9} m, depending on who is using that jargon term; and the separation between "UVC" and "UVB" may be at 280×10^{-9} m or 290×10^{-9} m, again depending on who uses the terms. Therefore, if names must be used, precise definition of their meaning is necessary (*6*). As will be seen, the presentation of spectral radiometric data is a way to avoid any confusion on this issue.

Measurement Systems and Instruments

The quantities listed in table 1 are measured with an instrument called a radiometer, and they include the radiant power (Φ) or energy (Q), which have units of watts (W) and joules (J), respectively. Irradiance (E) is the radiant power incident upon a surface per unit area of the surface and has units of $\mathrm{W\cdot m^{-2}}$, whereas radiance (L) is a quality of the source and is the radiant power emitted from a source per unit area of the source and into a unit solid angle. Radiance has units of $\mathrm{W\cdot sr^{-1}\cdot m^{-2}}$. The energy equivalents of irradi-

TABLE 1.—*Selected radiometric quantities, symbols, defining equations, and units*[a]

Quantity[b]	Symbol	Defining equation	Units (abbreviations)
Radiant energy	Q		Joule (J)
Radiant power	Φ		Watt (W)
Irradiance	E	$E=d\Phi/dA$	Watt per square meter ($W \cdot m^{-2}$)
Radiant exposure	H	$H=dQ/dA$	Joule per square meter ($J \cdot m^{-2}$)
Radiance	L	$L=d^2\Phi/d\Omega dA \cos \theta$	Watt per steradian per square meter ($W \cdot sr^{-1} \cdot m^{-2}$)
Integrated radiance	tL	$tL=d^2Q/d\Omega dA \cos \theta$	Joule per steradian per square meter ($J \cdot sr^{-1} \cdot m^{-2}$)

[a] For a more complete listing of quantities and units, *see* (*5*).

[b] Quantities may be restricted to a narrow wavelength band (first derivative with respect to wavelength) by adding the word "spectral" and indicating the wavelength. The corresponding symbols are changed by adding the subscript λ.

ance (E) and radiance (L) are radiant exposure (H) and integrated radiance (tL), respectively.

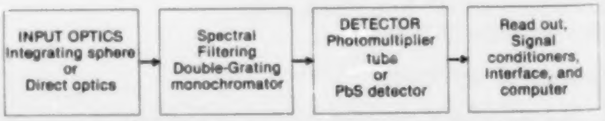
The major components of a radiometer include input optics, a detector, signal processing components (usually electronics), and the readout. The input optics are used to define the field of view and sometimes the wavelength response of the instrument. The input optics, therefore, are components that the light passes through or reflects from before it reaches the detector. Included here are components such as transmission filters, windows, lenses, mirrors, and the like. The detector can be a silicon or vacuum photodiode, a lead sulfide or pyroelectric detector, a calorimeter, or a PM tube.

For measurement of the spectral quantities, dispersive optics such as a prism or diffraction grating monochromator or band-pass filters are located before the detector in the system described in the preceding paragraph. In this case, "dispersive" means to break up the radiation into its separate components as a function of wavelength. In addition, a hollow sphere, whose inside surface has a diffusely reflecting white finish and is referred to as an "integrating sphere is commonly used in the input optics of a system which is used to measure the spectral quantities. Such a sphere provides the instrument with a uniform (cosine) angular response. A similar angular response can also be obtained with the use of a reflecting diffuser plate with a white finish. A more directional response can be obtained with the use of a transmissive plate of glass or quartz (fused silica) whose surface(s) has been ground or etched so that the incident optical radiation is diffused. Such diffusers are also sometimes used with radiometers to measure the radiometric quantities. Alignment of the optical system with respect to the source to be measured is usually much less critical with a system that uses a diffuser as opposed to a system that does not.

A functional block diagram of a spectroradiometer system used by the BRH to measure continuous wave or nonpulsed sources is shown in text-figure 1. Input optics for this system include selectable barium sulfate-coated integrating spheres with diameters of 3.81 cm (1.5 inches), 7.62 cm (3 inches), and 15.24 cm (6 inches) for the measurement of spectral irradiance or direct field-of-view optics for the measurement of spectral radiance. The input optics also include a filter wheel that allows placement of various short wavelength "cutoff" filters directly in front of the monochromator for spectral order-sorting purposes. The short wavelength cutoff filters eliminate radiation at wavelengths that would otherwise be simultaneously transmitted through grating monochromators when the desired radiation is at longer wavelengths—a characteristic of grating monochromators. The double-grating monochromator utilizes two sets of gratings to cover the wavelength range from 200×10^{-9} m through $2{,}500 \times 10^{-9}$ m, and it can be operated with various selectable bandwidths ranging from 1 to 20×10^{-9} m.

One set of gratings covers the wavelength range from 200 to 800×10^{-9} m, while the second set covers the wavelength range from 800 to $2{,}500 \times 10^{-9}$ m. The monochromator utilizes a precision stepping motor system to vary the wavelength being measured and to absolutely determine the monochromator's wavelength setting. A PM tube is used as a detector for measurements over the wavelength range from 200 to 800×10^{-9} m, whereas a lead sulfide detector is used for measurements in the IR region over the wavelength range of $800\text{–}2{,}500 \times 10^{-9}$ m. Further, both detectors are thermoelectrically cooled to −20°C to improve the signal-to-noise characteristics. The electronic signal from the detector, which is proportional to the light incident upon it, is amplified, converted to a digital signal, and displayed on the system control console in relative units of microamperes. A MIDAS electronic interface system acts as an intermediary and translates control signals (messages) from the system minicomputer (a NOVA 3D) to the spectroradiometer and converts data from the spectroradiometer into a computer-acceptable format. The minicomputer controls overall system functions, as well as analysis of the data, through the use of specialized software. The sensitivities for various wavelengths for this spectroradiometer system are listed in table 2 in both SI units ($W \cdot m^{-3}$) and more familiar conventional units ($W \cdot cm^{-2} \cdot nm^{-1}$). The dynamic range for this system is six decades. Another similar but field portable spectroradiometer system that uses a microprocessor and desk top calculator for data reduction and processing is described elsewhere (*7*). Instruments similar to those described in this paper are available commercially from several vendors.

For accurate characterization of a source, it is sometimes necessary to measure the temporal characteristics of the optical radiation emitted. The major components of a sys-



TEXT-FIGURE 1.—Block diagram of Optronic Laboratories' Model 747 laboratory scanning spectroradiometer system used to measure continuous wave or nonpulsed sources of optical radiation.

TABLE 2.—*BRH spectroradiometer system sensitivity with a 10-to-1 signal-to-noise ratio*

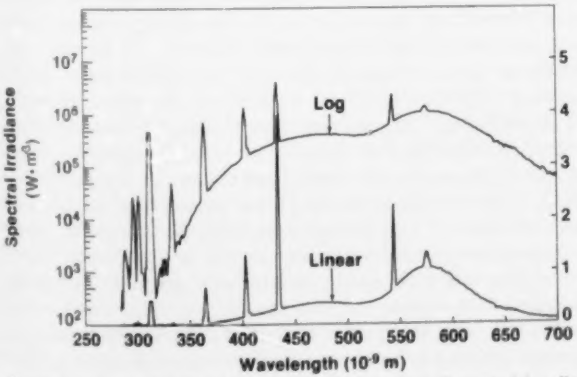
Wavelength range, 10^{-9} m	Sensitivity	
	$W \cdot m^{-3}$	$W \cdot cm^{-2} \cdot nm^{-1}$
200–250	10^{5}	10^{-8}
250–800	10^{4}	10^{-9}
800–2,500	10^{7}	10^{-6}
2,000–2,500	10^{8}	10^{-5}

tem to determine the temporal characteristics of pulsed or repetitively pulsed sources of optical radiation include input optics and a detector such as a photodiode or PM tube, with the addition of an oscilloscope as the signal readout. Care must be taken in the choice of the detector for this system to assure that its temporal response is much more rapid than any temporal characteristic of the radiation to be characterized. In addition, the bandwidth of the oscilloscope must be large enough so that it does not distort the shape of the pulse to be characterized.

There are several ways of displaying spectra data (*8*). Two are shown in text-figure 2, in which spectral irradiance data for a common fluorescent lamp at a distance of 2 m are plotted on both a logarithmic and linear scale as a function of wavelength over the range 250–700×10^{-9} m. From text-figure 2, it can be seen that an estimate of the spectral irradiance for wavelengths less than about 350×10^{-9} m can be obtained from the logarithmic plot, but not from the linear plot where the values are close to zero. Thus, in this case, the logarithmic plot is more useful. However, it is reasonable to use a linear plot when the spectral irradiance values are of the same order of magnitude over the wavelength range of interest.

Calibrations

Instruments for the measurement of power, energy, irradiance, or radiant exposure are usually calibrated with the use of electrically calibrated standard calorimeters (*9*) (e.g., calorimeters having a response that does not vary as a function of wavelength over a broad wavelength range). Spectroradiometers for the measurement of the spectral quantities are usually calibrated with the use of spectral standard lamps (*10*). Available standard lamps usually used for this purpose are listed in table 3. Since these standard lamps are calibrated at specific wavelengths over the wavelength range indictated, an interpolation procedure must be used to obtain values at intermediate wavelengths (*11*). Normally, the standard lamps are used to calibrate the instrument at the wavelengths of interest. The calibration factors obtained are then used to determine the values for the unknown source to be measured.



TEXT-FIGURE 2.—Semilogarithmic and linear plots of spectral irradiance for common fluorescent lamp at a distance of 2 m.

TABLE 3.—*Wavelength range and uncertainties associated with selected national spectral standard lamps*

Standard	Quantity	Wavelength range,[a] ×10^{-9} m	Uncertainty, ×10^{-9} m (%)	
Tungsten ribbon lamp	Spectral radiance	225–2,400	225	(2)
			1,000	(0.7)
			2,400	(0.6)
Quartz-halogen	Spectral irradiance	250–1,600	250	(2.6)
			555–1,100	(1.2)
Deuterium lamp	Spectral irradiance	200–350	200–350	(6)

[a] Standards of the National Bureau of Standards.

MEASUREMENT ERROR

Ultimately, the total uncertainty that may be associated with optical radiation measurement data should be specified. To accomplish this task, one must take into account the uncertainties that may be associated with the sources of error for each of the major components of the measurement system, including those associated with hardware components (input and dispersive optics, detector and electronics, and readout). Also, the operator and the instrument calibration can give rise to significant and large errors in the measurement data. The operator can be a source of error for both the calibration of the instrument and the subsequent measurements by not selecting proper components or by using poor operator techniques as discussed more fully elsewhere (*12*). With regard to calibration, it was noted in the preceding section that some uncertainty is associated with the calibration standards used. Some uncertainty is also associated with the transfer of the calibration to the instrument. These two sources of error must be accounted for so that a meaningful estimate of the uncertainty involved in the measurement data can be obtained.

The following is a list of selected sources of error in optical radiation measurements:

Alignment of optical components
Contamination of optical components
Degradation of optical components
Stray light (ambient)
Electronic noise
Meter response time
Nonlinearity of response
Accuracy of standards
General operator techniques
Stability of source
Temperature-dependent response
Lack of "out-of-band" rejection

While not a comprehensive listing, this list includes many of the important and common sources of error. More comprehensive discussions of sources of error in optical radiation measurements can be found elsewhere (*10, 12*).

Alignment of Optical Components

Alignment of optical components can become a very significant source of error, for example, when an instrument or measurement system is used that has a very narrow field of view or acceptance angle (e.g., 10^{-5} sr). For instance, in the measurement of radiance or spectral radiance, the slight misalignment of a lens used to image a small area of a relatively small source (e.g., an incandescent light bulb or a tungsten filament) onto the entrance aperture of the detector or monochromator can result in a significant error in the determination of the radiance of the source. In such a situation, the operator must use considerable care in aligning the lens or considerable error will result. The extent of the error can be estimated by repeated alignments and measurements.

Contamination and Degradation of Optical Components

Contamination of optical components is a very obvious source of error, but it is sometimes ignored. Dust, dirt, cigarette smoke, and fingertip grease on optical components such as lenses, mirrors, filters, and the like give rise to scattering and absorption of optical radiation and, therefore, to error. While the errors usually associated with contamination of optical components may be small, they should not be ignored. With regard to degradation of optical components, some components simply degrade with time. For example, it is well known that some thin-film interference filters degrade with time and the reflection and transmission characteristics of the filter change concomitantly (*12*). Errors associated with both contamination and degradation of optical components can be discovered by periodic checks on the calibration of the instrument. Degraded components should, of course, be either cleaned or replaced.

Ambient Stray Light

Ambient stray light can become a significant source of error when the order of magnitude of the radiation to be measured is the same as that of the ambient radiation. In such a situation, the operator must exercise care to take the ambient lighting or radiation levels into account either by eliminating them (e.g., turning off the room lights) or by measuring them and subtracting their contribution from the total reading.

Electronic Noise

Electronic noise, like ambient stray light, can become a significant source of error when the intensity of the signal of the radiation to be measured is of the same order of magnitude as that of the electronic noise of the measurement system itself (sometimes referred to as "darkage"). For weak signals, the darkage can give rise to a large uncertainty in the measurement data.

Meter Response Time

Meter response time or the rate at which the meter responds to the onset of radiation can be a source of error if the reading is taken before the instrument has had sufficient time to arrive at its true, final value. In this regard, it is important for the operator to account for the specific time constants for the instrument being used so that any uncertainty that may be associated with this source of error is minimized.

Nonlinearity of Response

Nonlinearity of response can become a significant source of error when the intensity of the radiation to be measured is very much larger or smaller than the intensity of the radiation associated with the calibration standard. In such cases, the accuracy of the reading obtained is dependent on the linearity of response of the measurement system. In some cases, the uncertainty may be fairly significant. Therefore, it should not be ignored for any measurement.

Accuracy of Standards and General Operator Technique

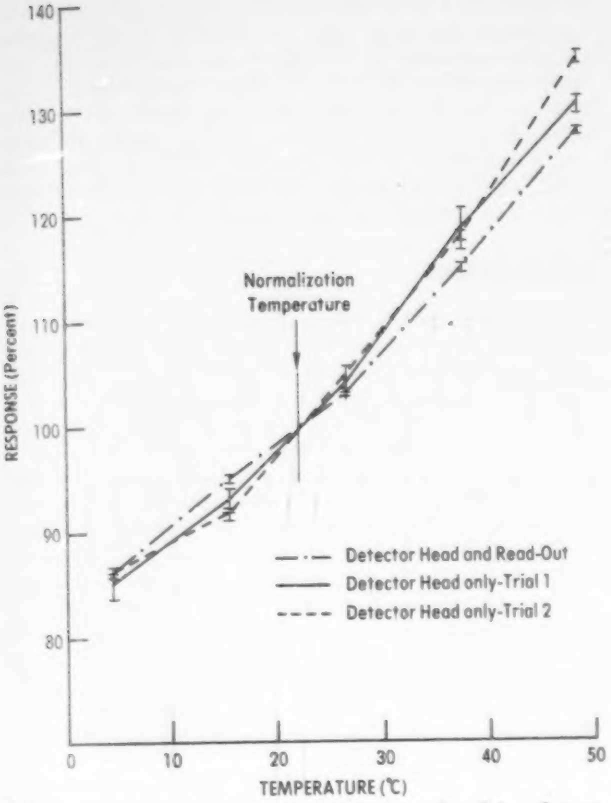
The uncertainties that may be associated with the calibration standards and general operator technique have been discussed in earlier sections of this paper and elsewhere (*8, 10, 12*).

Stability of Source

The instability associated with the source to be measured is unquestionably a source of uncertainty in measurement data. Further, the degree of the uncertainty is directly proportional to fluctuations of the radiation emissions from the source (i.e., the greater the instability, the larger the uncertainty).

Temperature-Dependent Response

The temperature-dependent response of some detectors can give rise to significant errors when measurements are made at an ambient temperature different from that prevailing when the instrument was calibrated. The temperature-dependent response for some detectors can be very large, as is illustrated in text-figure 3. There, the response of a biplanar vacuum photodiode at the helium–neon laser wavelength of 632.8×10^{-9} m is plotted in percent (normalized to 100% at 22°C) as a function of temperature over the range 4–50°C. For the detector tested, the temperature-dependent response near room temperature is about +0.3% per °C (*13*). Not all detectors and instruments have such a large temperature-dependent response. For example, the temperature-dependent response at the helium–neon laser wavelength of a p-i-n silicon photodiode instrument tested was found to be about −0.14% per °C near room temperature (22°C) (*13*). While the magnitude of the temperature-dependent response for the p-i-n silicon photodiode tested is not as large as that for the biplanar photodiode tested, it is still significant and should not be ignored if accurate mea-



TEXT-FIGURE 3.—Temperature-dependent response of an S-5 surface response biplanar vacuum photodiode detector head and instrument to 632.8×10^{-9} m laser radiation.

surements are to be made. Finally, it should be noted that even calorimeters have a small but measurable temperature-dependent response (*13*). The temperature-dependent response of detectors and instruments is discussed more fully elsewhere (*13*).

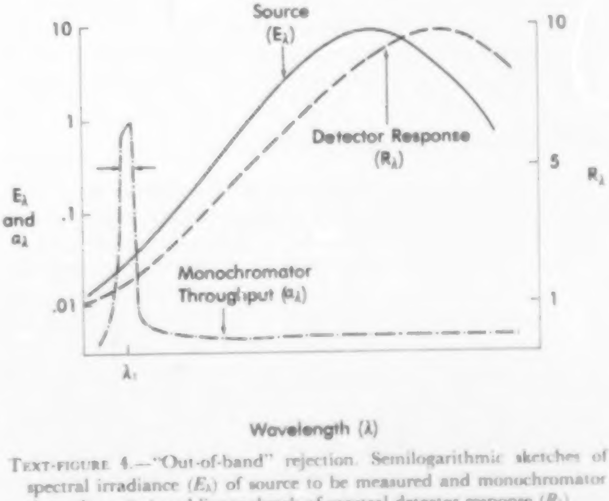
Out-of-Band Leakage

While there is measurement error associated with all of the aforementioned items, the final item, lack of out-of-band rejection or out-of-band leakage, is a major and common source of error that can give rise to very large uncertainties or error in measurement data. In fact, if care is not taken, an error here can lead to spurious results. Basically, out-of-band rejection refers to the ability of monochromators or filters to transmit radiation only in the selected band pass. The extent of the error associated with out-of-band leakage depends on the following three factors: 1) the spectral irradiance characteristics of the source to be measured, 2) the out-of-band rejection characteristics of the monochromator (slit function) or filter being used, and 3) the spectral response characteristics of the detector being used.

As an example, if these factors have the characteristics similar to those sketched in text-figure 4, then out-of-band leakage will give rise to large errors and uncertainty. In text-figure 4, the spectral irradiance of the source to be measured and the relative monochromator throughput (when the monochromator is set to transmit radiation in a small band centered at wavelength λ_1) are plotted on logarithmic scales, whereas the spectral response of the detector (R_λ) to be used is plotted on a linear scale. From text-figure 4, it can be seen that the intensity of the emissions in the out-of-band radiation over a broad wavelength range is much greater than the intensity of the within-band radiation centered at wavelength λ_1. Text-figure 4 also shows that when the monochromator is set to transmit radiation within the small band centered at wavelength λ_1, it also simultaneously transmits a small percentage of the out-of-band radiation. In this particular example, the intensity of the out-of-band radiation transmitted through the monochromator to the detector would be of the same order of magnitude as the intensity of the within-band radiation centered at wavelength λ_1. Also, in this instructive example, since the detector to be used is much more responsive (*see* linear plot R_λ in text-fig. 4) to the out-of-band radiation than it is to the within-band radiation centered at wavelength λ_1, the reading obtained from the detector will be due primarily to the out-of-band leakage radiation and not to the within-band radiation to be measured.

The combination of error-prone elements just described can occur when a measurement system utilizing a single-grating monochromator and a detector more sensitive to visible than to UV radiation is calibrated with a 1,000-W quartz-halogen lamp in the UV range. In one such situation of which the authors are aware, about 80% of the reading obtained was due to out-of-band leakage radiation. In that situation, a 1,000-W quartz-halogen lamp was being used to calibrate a single-grating spectroradiometer system at 250×10^{-9} m with a 10×10^{-9} m bandwidth. In another situation, an error in measurements as large as 10,000% due to out-of-band leakage with a filter radiometer has been reported (*10*).

It is possible to obtain an estimate of the error that may be associated with out-of-band leakage through the use of a



TEXT-FIGURE 4.—"Out-of-band" rejection. Semilogarithmic sketches of spectral irradiance (E_λ) of source to be measured and monochromator throughput (a_λ) and linear sketch of spectral detector response (R_λ).

simple cutoff filter which, in the example described in the paragraph above, would absorb almost all of the within-band radiation to be measured centered at wavelength λ_1. Measurements are made with and without the cutoff filter in the optical path. The reading without the filter in the optical path is due to both the within-band radiation to be measured and the out-of-band radiation, whereas the reading with the cutoff filter in the optical path is due to the out-of-band leakage radiation only. Thus, in this example, the reading obtained with the cutoff filter in the optical path, after correction for reflection losses from the surfaces of the filter, is a direct estimate of the out-of-band leakage. When out-of-band leakage has been identified as a significant source of error, several techniques can and should be used to minimize the extent of the error as described in the following paragraph.

Usually, out-of-band leakage can be a significant source of error with a single-grating spectroradiometer system. Therefore, an obvious solution is to use a high-quality double-grating monochromator with high out-of-band rejection characteristics instead of a single-grating monochromator (*8*). Another approach is to use a band-pass filter in the optical path of the input optics which has a relatively strong absorption for the out-of-band radiation but a relatively high transmittance for the within-band radiation to be measured. Finally, a detector that is much more sensitive to the within-band radiation than it is to the out-of-band radiation can be used. Such a detector for the measurement of UV radiation is referred to as a "solar blind" detector, and it is relatively sensitive to UV radiation but insensitive to visible and IR radiation. If these three techniques are combined, the errors that may be associated with out-of-band leakage can be minimized, if not entirely eliminated.

Estimates of Total Uncertainty

Once the uncertainty for each of the known sources of error has been determined, it is then possible to prepare an error budget and to obtain an estimate of the total uncertainty in the measurement data. A typical error budget for one spectroradiometer system for the measurement of spectral irradiance is shown in table 4. In table 4 are listed the uncertainties that were determined for significant and known sources of error in the process of measurement of spectral irradiance for quartz-halogen-type lamps. Other sources of error were determined to be insignificant for this system. In this example, the total uncertainty in the measurement process is conservatively estimated to be the linear sum of the uncertainties associated with each of the sources of error listed. The total measurement uncertainty is dependent on the lamp type. For instance, in this example, the total measurement uncertainty for quartz-halogen-type lamps was estimated to be less than 12.7%, while with this same system, the total uncertainty associated with the measurement of spectral irradiance for fluorescent-type lamps was estimated to be less than 26%. Thus the lamp to be measured by itself can be a significant source of uncertainty in the total measurement uncertainty.

CONCLUSIONS

Presentation of the results of radiometric measurements should clearly be done with the use of correct quantities and units. To reach this final step of presenting results, one must have an understanding of the measurement process and of the inherent uncertainties of the specific instruments used. All too often radiometric data are presented without a discussion of measurement errors, including an error budget and a statement of the estimated uncertainty in the data. On the basis of past experience, the validity of optical radiation measurement data reported without a discussion of the uncertainty in the data should be questioned. This is not to say that measurements made in photobiological experiments must have a small uncertainty. However, even if there is a substantial uncertainty in the data (>30%), the data should be reported. Since large errors in optical radiation measurements can and do occur, a discussion of errors and an estimate of the uncertainty in the data should always be presented with the data.

Molecular Aspects of Drug Photosensitivity With Special Emphasis on Psoralen Photosensitization Reaction[1,2]

Madhu A. Pathak[3]

ABSTRACT—Photosensitization reactions involve phototoxic reactions and photoallergic reactions, which are less common. Common drugs and chemicals that photosensitize humans are listed. Phototoxic reactions include the following: 1) direct photosensitization (type I reactions), in which the reactions of the triplet-state sensitizer are directly attributable to a component other than oxygen (e.g., DNA, proteins, and cell membranes), and 2) indirect photosensitization (type II reactions), in which the triplet state of a sensitizer reacts first with molecular oxygen, producing an "active oxygen" intermediate that subsequently reacts with the biologic system. The active oxygen intermediates are singlet oxygen ($^1O_2$), superoxide radical anions ($O_2^{\overline{\cdot}}$), and hydroxy radicals. Psoralen-induced skin photosensitization appears to involve both type I and type II reactions. The formation of monofunctional and bifunctional psoralen–DNA photoadducts (a type I reaction) is probably responsible for cell damage, cell death, mutation, and even skin carcinogenesis. The erythema response appears to be the result of a type II reaction.—JNCI 1982; 69:163–170.

In photobiology, it is well recognized that photons of certain wavelengths can be damaging to the cells. Absorption of photons, either directly or through energy transfer processes, by cellular constituents such as DNA, RNA, proteins, or lipoproteins can result in injury or damage to the cell nuclei, cell organelles, and cell membranes and can result in alterations of cellular proteins, in inactivation of enzymes, in mutagenesis, and even in carcinogenesis. The term "photosensitivity" has been interpreted in various ways and has often confused those who are unfamiliar with photon-induced cellular and molecular alterations in biological systems in general and cutaneous tissue in particular.

In simple terms, photosensitization may be defined as any observable change in a reaction system containing the biologic material *A* and the photosensitizer *S*, a change which occurs only as a result of irradiation of the mixture of *A* plus *S*. When such a biologic system is irradiated, the light-absorbing component *S* of a reaction system causes another component of the biologic system *A* to react to the absorbed radiation and to produce detectable biological changes. In this system, *S* may or may not be consumed in the reaction, but *S* most often significantly lowers the energy required to produce similar changes that radiation alone may be capable of evoking at significantly high radiation doses. In this presentation, a photosensitizing agent can be defined as a compound whose chemical configuration endows it with the ability to absorb UV radiation or visible radiation and to undergo a light-dependent photochemical reaction resulting in the generation of highly reactive, relatively metastable (long-lived) intermediate states (e.g., triplet state, free radical state, and ions) that cause chemical and functional modification in other molecules of biologic systems (*1, 2*).

In fair-skinned individuals, sensitivity to sunlight is a common clinical problem. The interface between humans and their environment is the skin, and the physical (light) and chemical agents acting directly on human skin are important etiologic or precipitating factors in photosensitivity disorders. Most often, toxic chemicals when applied locally are irritants to the skin, but in photosensitivity reactions, chemicals and drugs by themselves may not act as contact irritants and are generally innocuous to skin in the absence of light exposure. However, under certain circumstances when the skin is challenged with the proper concentration of certain agents (e.g., 8-MOP) and the appropriate wavelengths of radiation (e.g., 320–400 nm), light-induced undesirable skin reactions could be enhanced by the presence of photosensitizing agents (e.g., erythema, edema, vesiculation, and other skin eruptions). "Cutaneous photosensitivity" is a general term used to refer to the abnormal reactions of human skin to the stimulus of light (*3*). Drug photosensitivity reactions or chemical photosensitivity reactions may be defined clinically as adverse skin responses resulting from the combination of exposure to certain therapeutic or chemical agents and to UV or visible radiation. Adverse cutaneous reactions can occur in individuals who either have ingested certain drugs or have been in contact with certain chemicals (tables 1, 2). These reactions may include an acute, exaggerated sunburn response followed by pigmentation or such abnormal responses as eczematous and urticarial reactions, vesicles, bullae, and papules. There may be desquamation and hyperpigmentation or hypopigmentation. These adverse photosensitivity reactions are classified into two broad categories: 1) phototoxic reactions and 2) photoallergic reactions.

PHOTOTOXIC AND PHOTOALLERGIC REACTIONS

Phototoxic reactions (*3–8*) are those damaging reactions of cutaneous cells that are exaggerated by the dual effect of a chemical agent plus UV or visible radiation in which there is no evidence of the participation of the immune system. These reactions most often can be reproduced in almost

Table 1.—*Contact photosensitizers: Chemicals that induce photosensitivity reactions in humans*[a]

Name[b]	Use	Reported clinical observations
Halogenated salicylanilides; 3,3′,4′,5-tetrachlorosalicylanilide; 3,4′,5- and 3,3′,5-trichlorosalicylanilide; 3,4′,5- and 3,3′,5-tribromosalicylanilide; 3,5- and 4,5′-dibromosalicylanilide	Deodorant, bacteriostatic agents in soaps	Phototoxic and eczematous photoallergic reactions, burning, itching, cross-photosensitivity reactions
Hexachlorophene	Antimicrobial, antiseptic	Phototoxic reactions
Bithionol or bis(2-hydroxy-3,5-dichlorophenyl) sulfide	Antimicrobial, antiseptic	Photoallergic reactions
Fentichlor (2,2′-dihydroxy-5,5′-dichlorodiphenylsulfide); multifungin (bromochlorosalicylanilide); Jadit (4-chloro-2-hydroxybenzoic acid *N-n*-butylamide)	Antifungal	Phototoxic and photoallergic reactions
5-Fluorouracil	Antineoplastic	Acceleration of inflammatory process
PABA and esters of PABA	Suncreen	Photoallergic reactions
4,4′-Bis(3-phenylureido)-2,2′-stilbenedisulfonic acid or blankophor	Fluorescent brightening agent for cellulose, nylon, or wool fibers	Phototoxic and photoallergic reactions
Cadmium sulfide	In tattoos	Erythema
Furocoumarins: psoralen, 8-MOP, 5-methoxypsoralen, TMP	In vitiligo for increased pigment formation and sun tolerance	Marked erythema, vesicles, bullae, hyperpigmentation
Essential oils: oil of bergamot, oil of lime, oil of cedar, oil of lavender, oil of citron, oil of sandalwood	Cosmetics and beauty aids	Phototoxic reactions and postinflammatory hyperpigmentation
Plants: *Umbelliferae, Rutaceae*	Used in perfumes or flavorings or as spices	Phytophotodermatitis, hyperpigmentation, vesicles, bullae
6-Methylcoumarin	Used in cosmetics	Photoallergic reactions
Musk ambrette	Used in cosmetics	Photoallergic reactions
Dyes: fluorescein, rose bengal, eosin, erythrocine, trypaflavin, orange red, paraphenylenediamine, methylene blue, toluidine blue, trypan blue, anthraquinone	Cosmetics and dye industry	Erythema, edema, vesicles, pigmentation, phototoxic reaction
Coal tar and coal tar derivatives containing anthracene, phenanthrene, naphthalene, thiophene, and many phenolic agents; pitch; acridine	In therapy for psoriasis and chronic eczema; in hair shampoos	Smarting, exaggerated sunburn, urticarial wheals, tar melanosis

Sunlight and man: Normal and abnormal photobiologic responses. Tokyo: University of Tokyo Press, 1974:3–14, with permission.

[b] PABA=*p*-aminobenzoic acid.

every individual if an appropriate concentration of the agent is either applied topically or given orally and enough light energy of the appropriate wavelengths is delivered to elicit the reactions. Light plus the offending agent leads to an exaggerated sunburn reaction with or without painful edema, vesicles, and subsequent hyperpigmentation. The reaction usually is confined to the site of exposure and can occur within 5–18 hours after exposure to the sun and is maximum between 36 and 72 hours post exposure. Subsequent hyperpigmentation and desquamation can also occur. The severity depends on the route of entry of the chemical. Substances such as psoralens, pitch, tar, anthracene, and synthetic dyes, which when applied topically can readily reach the viable cells of the skin, may give early symptoms (e.g., burning, smarting, and itching sensations). Bullae or small vesicles may develop if the concentration of the implicated agent or if the exposure dose of UV or visible radiation is high.

Certain phototoxic reactions require the presence of molecular oxygen (e.g., hematoporphyrin or several xanthine dyes such as eosin and rose bengal). In such reactions, the triplet state of the photosensitizer reacts first with molecular oxygen, producing an active oxygen intermediate that subsequently reacts with a biologic substrate (*9*, *10*). The reactive oxygen intermediates are singlet oxygen ($^1O_2$), the superoxide anions (O_2^-), and hydroxy radicals. This oxygen-dependent reaction is referred to as a photodynamic reaction or type II reaction. However, many phototoxic reactions can occur in the absence of oxygen (e.g., psoralen and chlorpromazine photosensitization), and these oxygen-independent reactions are often referred to as drug or chemical photosensitization reactions (type I reactions). Although the term "photosensitization" (*11*, *12*) was originally proposed to indicate oxygen-independent biological sensitization reactions induced by psoralens, its current usage has now been expanded to include several other therapeutic agents and other chemicals used in cosmetics, food preservatives, hair dyes, fragrances, industrial products and by-products, and agricultural items (*3–8*). In a type I reaction, the so-called direct reaction, the triplet state of the sensitizer reacts directly with the key component of the biologic substrate, either through the hydrogen or the electron transfer process (*10*). In most of the drug or chemical photosensitization reactions, wavelengths that evoke abnormal reactions are usually but not always in the UV spectrum, which encompasses the 290–400 nm region. Most reactions have been reported to require UVA radiation (320–400 nm); however, certain phototoxic reactions can be initiated by UVB radiation (290–320 nm) as well as by visible radiation (400–700 nm).

Photoallergy to drugs is an acquired, altered capacity of the skin to respond to light in the presence of a light-absorbing chemical and involves the immune system (*3–8*). The absorbed light energy may promote a photochemical reaction between the drug that absorbs the radiation and the skin proteins. The drug may act to form a haptenic group, and it may either photoreact directly with skin proteins to form a "photoantigen" or first become photo-

Name	Uses	Clinical observations	Action spectrum, nm
Sulfonamides: sulfanilamide, sulfathiazole, sulfapyridine, sulfamethazine, sulfaguanidine, sulfisoxazole, monochlorphenamide	Chemotherapy, antibacterial agents	Phototoxic and photoallergic reactions	290–320
Sulfonylurea: carbutamide, tolbutamide (Orinase), chlorpropamide (Diabinese)	Hypoglycemic or antidiabetic drugs	Phototoxic reactions	290–360
Chlorthiazides:			
6-Chloro-7-sulfamyl-3,4-dihydro-1,2,4-thiodiazine 1,1-dioxide (HydroDiuril)	Diuretics, antihypertensive	Papular and edematous eruption, plaques	290–320
Quinethazone (Diuril)	Antihypertensive	Phototoxic and photoallergic reactions	320–400
Phenothiazines: chlorpromazine (Thorazine), promethazine (Phenergan), mepazine, Stelazine, trimeprazine, Compazine, promazine (Sparine)	Tranquilizer, nematode infestation agent, urinary antiseptic, antihistamine	Exaggerated sunburn, maculopapular and urticarial eruptions, gray-blue hyperpigmentation	290–400
Antibiotics:			
Demethylchlortetracycline (Declomycin), chlortotracycline, oxytetracycline, doxycycline	Broad-spectrum antibiotic	Exaggerated sunburn, phototoxic reaction	320–400
Griseofulvin	Antimycotic	Exaggerated sunburn, phototoxic and photoallergic reactions	320–400
Nalidixic acid (NegGram)	Antibacterial	Erythema, bullae	320–400
Furocoumarins: TMP (trioxsalen), 8-MOP (methoxsalen), psoralen	In photochemotherapy of psoriasis and vitiligo; for sun tolerance and increased pigment formation	Erythema, bullae, hyperpigmentation	320–400
Estrogens and progesterones:			
Mestranol and norethynodrel, diethylstilbesterol	Oral contraceptives	Melasma, phototoxic reactions	?290–320
Chlordiazepoxide (Librium)	Tranquilizer, psychotropic	Eczematous eruption	290–360
Triacetyldiphenolisatin	Laxative	Eczematous photoallergic reaction	290–320
Cyclamates, calcium cyclamate, sodium cyclohexylsulfamate	Artificial sweeteners	Phototoxic and photoallergic reactions	290–360

[a] This table has been adapted and reproduced from Fitzpatrick TB, Pathak MA, Harber LC, Seiji M, Kukita K. An introduction to the problem of normal and abnormal responses of man's skin to solar radiation. In: Fitzpatrick TB, Pathak MA, Harber LC, Seiji M, Kukita A, eds. Sunlight and man: Normal and abnormal photobiologic responses. Tokyo: University of Tokyo Press, 1974:3–14, with permission.

chemically altered by the absorbed energy. This photochemically altered haptenic group then reacts with the proteins to form an antigen. The photoantigen is then processed by macrophages and is presumed to come in contact with T-lymphocytes to manifest any ordinary type of delayed hypersensitivity immunologic response. The complete photoantigen is recognized on subsequent exposure to sensitized T-lymphocytes in the form of eczematous or papulovesicular eruptions in a patient. As in allergic eczematous contact dermatitis, cross-reactivity with structurally related chemicals or drugs may be seen in drug-induced photoallergy.

Although photoallergic contact dermatitis has been shown to involve immunologic mechanisms by such techniques as patch testing, histopathologic criteria, the use of passive transfer, lymphocyte stimulation test, and macrophage inhibition (*8–13*), it may be difficult to distinguish clinically between a chronic phototoxic reaction and a photoallergic reaction. The clinical manifestations in drug-induced photoallergic reactions may range from acute urticarial lesions to eczematous or papular lesions appearing within 24 hours or later. The eruptions may extend beyond the exposure sites. In recurrent cases, flare-ups of the distant, previously uninvolved sites may also occur. The effective radiation is generally in the UVA region (320–400 nm), although some reactions may be triggered by UVB (280–320 nm) radiation also. Generally, less concentration of the drug and less energy of UV radiation are required in photoallergic reactions than are necessary for the production of phototoxic reactions (*8, 13*). The various topical agents and systemic therapeutic drugs involved in phototoxic and photoallergic reactions in humans are listed in tables 1 and 2.

PHOTOREACTIVITY OF PSORALENS AND ISOPSORALENS

Furocoumarins (*14–23*) are heterocyclic, aromatic compounds derived from the condensation of a furan ring with a coumarin ring. Although this condensation may occur in several ways, in nature, however, only two forms of furan and coumarin fusion are generally seen: 1) a linear tricyclic structure resembling psoralen and 2) a nonlinear angular structure called angelicin (or isopsoralen) (text-fig. 1).

Linear psoralens (e.g., 8-MOP and TMP) and nonlinear psoralens (e.g., angelicin or isopsoralen and other methylated isopsoralens) when dissolved in ethanol or water exhibit a well-defined UV absorption spectrum with several characteristic peaks; the first peak is in the region of 300–335 nm, and the second is in the region below 330 nm (210–220 nm, 245–265 nm). The absorption band at 300–330 nm is attributable to $\pi \rightarrow \pi^*$ transition. When the photoreactive psoralens (e.g., 8-MOP and TMP) absorb radiation of 300–330 nm, the molecules are photoexcited to a short-lived (10^{-8} sec) ^{1}Ps. From this singlet excited state, certain potent photosensitizing molecules (e.g., 8-MOP and TMP) undergo

an intersystem crossing and are converted into the much longer-lived (10^{-3} sec) ^{3}Ps (text-fig. 2).

From the short-lived ^{1}Ps (10^{-8} sec) and the long-lived ^{3}Ps (10^{-3} sec), three events tend to occur: 1) a radiative decay, 2) a nonradiative transfer of energy (type I reaction), and 3) singlet oxygen production (type II reaction). In the radiative decay, the absorbed energy is dissipated either in the form of fluorescence (^{1}Ps to Ps_0) or in the form of phosphorescence (^{3}Ps to Ps_0) with the emission of light. This emitted energy may activate other molecules, but it may be wasted and not utilized in photochemical reactions. In the nonradiative transfer of energy from ^{3}Ps to biologic substrates, the triplet-state psoralen leads to certain specific chemical reactions which include *a*) dimerization of psoralens in which two psoralen molecules tend to react with each other and form both fluorescent and nonfluorescent dimers, *b*) C_4 addition to pyrimidines involving photochemical reaction with pyrimidine bases of nucleic acids, or *c*) photoreaction with amino acids of proteins. In the dimerization of psoralens, the formation of nonfluorescent dimers appears to dominate this reaction and involves C_4 dimers in which the 3:4 double bond of each psoralen molecule conjugates to form C_4 cycloadducts (text-fig. 1). The fluorescent dimers involving the 4′:5′ double bond are formed but usually in a lesser amount. The nonradiative reaction involves the formation of singlet oxygen by the transfer of energy from the photoexcited psoralen to any oxygen molecule, which leads to the formation of singlet oxygen.

The formation of photodimers from various furocoumarins has been reported by several workers (*18–21*). The characteristic absorption band in the range of 300–340 nm of monomeric psoralens disappears when photodimerization involving the 3:4 double bond occurs. The resultant dimerized product is devoid of the absorption band at 300–340 nm, and the product is nonfluorescent. The photodimers are nonphotosensitizing. They do not induce erythema and do not conjugate with DNA; however, they tend to be adsorbed and bind with epidermal proteins. The nature of this binding is, however, not covalent (*15*).

The photoreaction of psoralens with pyrimidines is one of the most important photochemical reactions which is not only of interest to photobiologists but is also of interest to dermatologists and geneticists. This reaction is responsible for elucidating the mutagenicity, carcinogenicity, and therapeutic effectiveness of psoralens in such diseases as psoriasis. The major photoreactions are schematically presented in text-figures 1 and 2 (*1–3*).

When linear psoralens are allowed to photoreact with pyrimidine bases (e.g., thymine, cytosine, or uracil) in the UVA region (320–365 nm) at room temperature in an aqueous solution, a decrease of the UV absorption band in

the region of 300–330 nm is seen, and a C_4 cycloaddition reaction product between the 3:4 double bond of psoralen and 5:6 double bond of pyrimidine occurs (*15, 22, 23*), which is nonfluorescent. In contrast, if the corresponding nucleosides or nucleotides of thymine or cytosine are allowed to react with psoralen in a frozen aqueous state in which the molecules are immobilized in an ice matrix, the formation of two types of new photoproducts can be demonstrated: 1) a fluorescent C_4 adduct and 2) a nonfluorescent C_4 adduct. The psoralen molecule has two reactive double bonds: the 4′:5′ double bond of the furan rings and the 3:4 double bond of the pyrone ring (*15, 16*). The psoralen can photoreact either at its 4′:5′ double bond or at its 3:4 double bond. When 4′:5′ double bond of psoralen photoreacts with 5:6 double bond of thymine, the resulting adduct is a fluorescent product; whereas if psoralen photoreacts at its 3:4 double bond with 5:6 double bond of thymine, the adduct is nonfluorescent. The 3:4- and 4′:5′-cycloadducts have different properties and UV absorption spectra (*24*). These two photochemical reactions are extremely important in understanding the reactivity of psoralens with DNA. The 3,4-cycloadduct usually does not further photoreact, whereas the 4′,5′-cycloadduct can be further photoexcited and give a second cycloaddition product with another pyrimidine base belonging to the opposite strand of DNA and can thus give rise to an interstrand cross-linkage, an event often very damaging to the cell (*15, 16*).

The photoreactions of linear and angular psoralens with DNA are schematically shown in text-figure 1. The first step involves the formation of a molecular complex between a furocoumarin and DNA; it occurs in the dark and involves the weak, hydrophobic van der Walls forces and hydrogen bonding (*24, 25*). The extent of this complex formation determines the rate of photoreaction and the number of psoralen molecules that form monofunctional and bifunctional adducts. Irradiation of this intercalated furocoumarin DNA complex gives rise to monofunctional and bifunctional (interstrand cross-linkage) adducts. Linear psoralens, like 8-MOP, TMP, and 5-methoxypsoralen, exhibit all three types of adducts with DNA; the angular isopsoralens (angelicin) have a remarkably low photobinding ability to DNA. Methyl-substituted psoralens (e.g., 4-methylpsoralen, 4,5′-dimethylpsoralen, and TMP) exhibit a greater ability to photobind with DNA than do nonmethylated psoralen molecules. Likewise, methyl-substituted isopsoralens (e.g., 5-methylisopsoralen and 4,5′-dimethylisopsoralen) also show a greater ability to bind with DNA than does the nonmethylated angelicin (*16, 24, 26–31*).

The interaction of furocoumarins (e.g., psoralen, 8-MOP, and TMP) and proteins (e.g., plasma proteins, albumin, globulin, and skin keratin) is not as strong as the photoreaction of psoralens with DNA or RNA. This weak interaction of furocoumarins with protein involves the 1) noncovalent conjugation in which the furocoumarins are bound by the weak forces of hydrogen bonding, 2) covalent photobinding of furocoumarins to certain amino acids in a protein molecule [this photoconjugation is not a major reaction (*15, 32*), and 3) photo-oxidation of certain amino acids. It appears that psoralens can photo-oxidize certain amino acids (e.g., histidine, cystine, and methionine). Preliminary evidence obtained in our laboratory suggests that the tryptophan of albumin also can be photo-oxidized by 8-MOP. It should be realized, however, that the interaction of psoralens with proteins is not a major photochemical reaction.

PSORALENS AND SINGLET OXYGEN PRODUCTION (TYPE II REACTIONS)

As stated earlier, certain phototoxic reactions require the presence of molecular oxygen (e.g., hematoporphyrin and several dyes). These oxygen-dependent reactions are referred to as photodynamic reactions (*9, 10*). The mechanism by which many photodynamic agents exert their photo-oxidizing action on biological substrates or other organic substrates involves the transfer of the photoexcitation energy to oxygen molecules present in the biologic milieu, i.e., the living cells. The normal oxygen molecule usually exists in the triplet state. The transfer of excitation energy of the photosensitizer S to the oxygen in its triplet state (${}^3O_2$) results in the formation of a very reactive singlet oxygen (${}^1O_2$) molecule, which causes the oxidation of the biological substrate. This may also lead to the formation of superoxide anions and hydroxy radicals. Interactions of these reactive species with biological substrates lead to the photo-oxidation of important cellular constituents essential for the viability and reproducibility of cells. This indirect reaction, often referred to as a type II reaction and involving a reactive species other than the light-absorbing molecule, can induce photosensitized damage to DNA, proteins, cell membranes, mitochondria, and other cellular components. The schematics of this reaction, in consecutive order, are as follows: $S_0 \xrightarrow{h\nu} {}^1S$, ${}^1S+{}^3O_2 \rightarrow S_0+{}^1O_2$, and ${}^1O_2$+biologic substrate→ photo-oxidation products.

These oxygen-dependent photodynamic reactions often cause vasodilation and are manifest as severe erythema, edema, and even bullae or vesiculation. It should be noted that the arterioles, venules, and capillaries which often become damaged in photosensitization reactions of the skin contain high concentrations of molecular oxygen. Formation of ${}^1O_2$ is thus a most likely event responsible for endothelial cell damage and subsequent vasodilation. The drug-induced or chemical photodynamic reactions involve photo-oxidative damage to DNA (e.g., oxidation of guanine), RNA, lysosomes (e.g., membrane damage, lipid oxidation, and liberation of hydrolytic enzymes), cell membranes (e.g., oxidation of lipids and formation of peroxides), and amino acids (oxidation) in proteins, including induction of cross-linkages in proteins.

Although it has long been recognized and carefully documented (*12, 15, 16*) that biological photosensitization involving psoralens was independent of oxygen and little or no photo-oxidation was involved when psoralens reacted in the presence of oxygen or other oxidizable substrates, recent evidence suggests that photoactivated psoralens can concomitantly induce type II reactions in vitro and in vivo (*33*). As early as 1961, Pathak et al. (*33*) demonstrated that photosensitizing psoralens in the presence of water or ethanol and oxygen exhibited a low-temperature phosphorescence and produced UV-induced free radicals. Cannistraro and Van de Vorst (*34*) also presented electron-spin resonance and optical absorption evidence for free radical involvement in the photosensitization action of furocoumarins and for their singlet oxygen production. Recently, Poppe and Grossweiner (*35*) demonstrated that 8-MOP and other psoralen derivatives in aqueous solution acted as photodynamic sensitizers and were able to produce biologic sensitization via the singlet oxygen mechanism by means of a type II or indirect photosensitization reaction that involved energy transfer from the excited triplet state of the psoralen derivative to oxygen. Studies by these investigators revealed that 8-MOP in the presence of UVA radiation and molecular oxygen generated $^1O_2$ by a triplet energy transfer reaction and that $^1O_2$ could inactivate lysozyme; if the irradiation was done in the absence of oxygen, no such inactivation occurred. Furthermore, they showed that the inactivation of lysozyme was much more evident when the psoralens were reacted in a deuterated water solution in the presence of oxygen, but the inactivation of lysozyme was strongly quenched when the reaction was done in the presence of a double-stranded polydeoxyribonucleotide, with which furocoumarins form intercalated complexes.

Veronese et al. (*32*) confirmed the inactivation of lysozyme by irradiation at 365 nm in the presence of 8-MOP and commented that this singlet oxygen effect of 8-MOP was very small when the effects were compared for the inactivation of several other enzymes in analogous reaction systems involving other well-known photodynamically active dyes such as rose bengal and methylene blue, which are known to produce singlet oxygen. Comparative studies involving the photo-oxidation of 17 amino acids revealed that limited oxidation (5–10%) of cystine, methionine, and histidine but no oxidation of tryptophan or tyrosine had occurred when 8-MOP was used as a photosensitizer. Singh and Vadsaz (*36*) also found that $^1O_2$ was the major reactive species produced in the inactivation of *Escherichia coli* ribosomes induced by the photosensitizing action of 8-MOP and TMP.

The formation of singlet molecular oxygen ($^1O_2$) by an energy transfer mechanism from the excited 8-MOP molecule (type II reaction) was also reported by DeMol et al. (*37*). This was done in three ways: 1) In the reaction of irradiated 8-MOP with $^1O_2$ acceptor 2-methyl-2-pentene, the characteristic oxidation products 2-methyl-3-pentene-2-ol and 2-methyl-1-pentene-3-ol could be identified; 2) the rate of 8-MOP-sensitized photo-oxidation with dopa (3,4-dihydroxyphenylalanine) mediated by $^1O_2$ was larger in D_2O than the rate was in water; and 3) the β-values for the reaction of $^1O_2$ with dopa in the presence of 8-MOP were in accord with the $^1O_2$-mediated photodecomposition reaction.

Even though the formation of singlet oxygen and superoxide anions with furocoumarins plus UVA in the presence of oxygen may be small, the effects may be extremely important in the explanation of the vascular damage that these photoreactive linear furocoumarins produce in the form of visible erythema and vesiculation reactions. These reactions appear to be analogous to those of porphyrins which produce endothelial cell damage and subsequent erythema. Interestingly, isopsoralens (e.g., angelicin and 5-methylangelicin) do not induce $^1O_2$ formation nor do they evoke cutaneous photosensitization in the form of the erythema reaction (*38*).

MONOFUNCTIONAL AND BIFUNCTIONAL ADDUCTS OF PSORALEN WITH DNA

The formation of psoralen–DNA photoadducts (monofunctional and bifunctional or interstrand cross-linkages) represents a type I reaction. The induction of monofunctional and bifunctional C_4 or C_4 adducts of psoralen with DNA signifies cell damage. Essentially, the role of monofunctional and bifunctional adducts appears to inhibit cell growth, induce lethality of cells, and inhibit DNA synthesis. These events subsequently can give rise to error-prone repair and mutagenicity. The extent of inhibition of DNA synthesis, inhibition of the template activity, and mutagenicity appear to be related more to the capacity of a given compound to form monoadducts rather than to the capacity to form interstrand cross-linkages. The degree of lethality can be correlated with the extent of the formation of bifunctional adducts (interstrand cross-linkages).

The question concerning the precise role of monofunctional and bifunctional adducts of psoralen with DNA in the induction of erythema reaction is difficult to assess. The studies reported by Musajo et al. (*16*), Rodighiero et al. (*28*), and Dall'Acqua et al. (*29*) and our own studies (*38–41*) indicated that skin photosensitizing activity can be correlated with the capacity to induce cross-linkages and not with the total photobinding of the furocoumarin to DNA.

On the basis of the observed correlation between skin photosensitization (erythema reaction) and the ability to form cross-linkages, it has been generally assumed that only cross-linking furocoumarins are able to induce skin photosensitization, and those furocoumarins that did not form interstrand cross-linkages were incapable of inducing the erythema reaction of the skin. For example, methyl-substituted isopsoralens (e.g., 5-methylangelicin, 4,5′-dimethylangelicin, and 3-carbethoxypsoralen) conjugate quite well with DNA, both in vitro and in vivo (*40, 41*), but they do not exhibit skin photosensitization reactions. These compounds form only monofunctional adducts and due to structural limitations, group substitutions, and steric hindrances do not form any cross-linkages. This observation supports the thesis that psoralen–DNA cross-linkages are in some way responsible for skin photosensitization and erythema reaction.

In my opinion, the photoconjugation of psoralen to DNA has very little to do with the induction of erythema, a reaction indicative of skin photosensitization. The event leading to the formation of psoralen–DNA adducts represents cellular damage, which in most instances leads to cell death but not to vasodilation. If cross-linking events were essential for the induction of an erythema reaction, then UVB (290–320 nm) radiation should be nonerythemogenic because it does not form any cross-linkages. The sunburn-producing UVB spectrum forms either thymine dimers or mixed dimers of other pyrimidine bases, and yet it is highly erythemogenic. Isopsoralens (e.g., angelicin and 5-methylangelicin), however, form single-strand adducts with pyrimidine bases but do not induce the erythema reaction. This damage to DNA is very similar to the damage caused by UVB radiation, an indication that the monofunctional adduct-forming event and the cross-linking event are not contributing to the induction of the erythema reaction.

The erythema reaction appears to be related to the ability of psoralen molecules to form singlet oxygen or superoxide anions. Nearly all photosensitizing molecules that evoke cutaneous photosensitization reaction (e.g., erythema and edema) are able to form the reactive oxygen species that subsequently reacts with biologic target molecules. For example, linear psoralens (e.g., 8-MOP, TMP, and psoralen) when irradiated in an oxygen-saturated system do show the formation of singlet oxygen. Nonlinear psoralens (e.g., angelicin, 5-methylangelicin, and linear psoralens such as 3-carbethoxypsoralen, 8-hydroxypsoralen, 5,8-dihydroxypsoralen, and 4′,5′-dihydroxypsoralen) forming only monofunctional adducts do not reveal any evidence for the formation of singlet oxygen (*38*). Furthermore, certain porphyrins (e.g., hematoporphyrin, uroporphyrins of types I and II, coproporphyrins of types I and II, and protoporphyrin) when exposed to radiation of 400–440 nm in the presence of O_2 can photosensitize the skin, induce an erythema reaction, and also form reactive singlet oxygen. The formation of $^1O_2$ can be demonstrated in D_2O and in quenching experiments in which $^1O_2$ quenchers such as histidine or dopa are also used (*41*, *42*). Thus psoralen-induced photosensitization reactions now appear to involve both type I and type II reactions, and both reactions can occur simultaneously in a biologic system such as the skin.

SUMMARY

Photosensitization may be defined as a process in which the combined action of a chemical or a drug and an appropriate wavelength of UV or visible radiation absorbed by the chemical or the drug leads to damaging effects in a biologic system, effects usually not observed in the absence of either modality. Absorption of radiant energy by the photosensitizer results in the generation of photoexcited states. Both the singlet excited state and the metastable (long-lived) triplet excited state of the photosensitizer can initiate chemical reactions with those components of the biologic system in close proximity to the photosensitizer. Drug-induced photosensitization reactions involve phototoxic reactions which are more frequent and photoallergic reactions which are less common. Common drugs and chemicals that cause phototoxic and photoallergic reactions in humans are listed in tables 1 and 2. Phototoxic reactions may be of two types: 1) Direct mechanisms, termed "type I reactions," are those in which the reactions of the triplet-state sensitizer are directly attributable to the key component of the biologic substrate other than oxygen (e.g., DNA, proteins, and cell membranes). 2) Indirect mechanisms, termed "type II reactions," include those reactions in which the triplet state of a sensitizer reacts first with molecular oxygen, producing an "active oxygen" intermediate that subsequently reacts with the biologic system. The active oxygen intermediates are singlet oxygen ($^1O_2$), superoxide radical anions (O_2^-), and hydroxy radicals. Interaction of these reactive oxygen species with biological substrates results in the photo-oxidation of molecules. Drug-induced photoallergic reactions appear to involve photoimmunologic mechanisms in which the drug or chemical acts as a haptenic group, and the absorption of the appropriate radiation wavelengths by the haptenic group of the drug causes photoconjugation with a carrier protein, resulting in the formation of a photoantigen. The biochemical avidity of the chemical or drug toward cellular constituents determines the site of reaction (whether in the nucleus or cytoplasm or with the proteins, cell membrane components, etc.). The psoralen-induced photosensitization reaction now appears to involve both type I and type II reactions. Until recently, it has been stated that oxygen is not required in biological photosensitization by furocoumarins (psoralens) and that the direct mechanism (type I) in which triplet-state psoralen reacts directly with the biologic substrate (e.g., DNA) was responsible for cutaneous photosensitization reactions. Recent evidence, however, suggests that the indirect mechanism involving the energy transfer and formation of an activated oxygen species [e.g., singlet oxygen ($^1O_2$), superoxide radical anions (O_2^-), and hydroxy radicals] also is responsible for manifesting the cutaneous photosensitization reaction. The formation of psoralen–DNA photoadducts (monofunctional and bifunctional or interstrand cross-linkages) represents a type I reaction, and these photoproducts are probably responsible for cell damage, cell death, mutation, and even for such phenomena as skin carcinogenesis. The psoralen-induced photosensitization reaction as manifested by erythema appears related to the formation of reactive singlet oxygen and superoxide anions, and it involves the energy transfer mechanism or type II reaction.

Immunosuppressive Effects of Ultraviolet (280–320 nm) Radiation and Psoralen Plus Ultraviolet (320–400 nm) Radiation in Mice[1,2,3]

Margaret L. Kripke[4,5]

ABSTRACT—Contact hypersensitivity (CHS), a cell-mediated immunologic reaction, can be induced in mice by application of a contact-sensitizing chemical to the shaved skin. Exposing the animals to UV radiation from FS40 sunlamps inhibits this immune response. This inhibition is systemic, since the sensitizer need not be applied to the irradiated site of the animal. The mechanism whereby UV radiation prevents CHS appears to involve the production of suppressor T-lymphocytes. Recent evidence suggests that UV exposure of mice alters the way in which certain antigens are processed, and this altered processing or presentation of antigen results in the activation of the suppressor cell pathway, rather than leading to immunization. Treatment of mice with a photosensitizer, psoralen, plus UV (320–400 nm) radiation also suppresses CHS systemically, but whether the cellular mechanisms are the same as those underlying the suppression from the shorter UV wavelengths remains to be determined. The possible role of these immunosuppressive events in photocarcinogenesis is discussed.—JNCI 1982; 69:171–173.

Studies reviewed here concern the effects of UV radiation on the response of the host to certain chemicals that are applied topically. These particular chemicals all have the property of inducing CHS (allergic contact dermatitis), which is a specific type of immunologic response mediated by T-lymphocytes. Furthermore, the interaction between these chemicals and UV radiation is an indirect one. In contrast to chemical photosensitization, in which the radiation acts directly on the chemical agent to produce its biologic effect, the phenomenon that we are dealing with involves an effect of UV radiation on the host. This effect on the host alters the way in which the host subsequently responds to the chemical agent. In addition to being an interesting biological phenomenon, perhaps with some practical applicability, it is quite likely that this UV radiation-induced alteration has important consequences for carcinogenesis in skin.

CONTACT HYPERSENSITIVITY

To understand the effects of UV radiation on the host, one should know something about the mechanisms involved in the CHS reaction. CHS is an immune reaction of the delayed hypersensitivity type, the prototype of which is the tuberculin reaction. This state of immunity is transferable with T-lymphocytes, not with antibody; thus it is generally referred to as a cell-mediated immune response. Although many important details concerning how this reaction occurs are unknown, the sequence of events can be envisaged in the following simplified manner.

After gaining entry to the body, a foreign substance (antigen) becomes associated with a cell of macrophage lineage. Whether this association involves phagocytosis and alteration of the antigen by the macrophage ("antigen processing") is not clear. The antigen, in association with a specific cell surface marker on the macrophage (Ia molecule), is then "presented" to a T-lymphocyte that reacts specifically with that antigen. This interaction between the T-lymphocyte and the antigen plus Ia molecule activates the lymphocyte to undergo division and differentiation. This amplification process (or sensitization) results in the formation of a new population of T-lymphocytes that is long-lived and is capable of reacting again with the same antigen. A subsequent encounter with this same antigen triggers the effector or efferent portion of the immune response, which involves the production by the lymphocytes of soluble mediators, including vasoactive agents and proliferative and chemotactic substances, that act on other cells of the reticuloendothelial system. This second amplification process requires several hours to occur and usually reaches a maximum only after 24–48 hours. The infiltration of these cells, mainly blood monocytes and lymphocytes, into the site of antigen deposition in the skin accounts for the induration that characterizes this reaction.

CHS is a special form of delayed hypersensitivity in which the antigen (or contact allergen) is a reactive molecule that binds to cells and proteins in the skin following topical application. Thus the antigen is actually a chemically modified component of the host. A second distinctive feature of

the CHS reaction is that the processing and presentation of the antigen are probably performed by special cells distributed in network fashion throughout the epidermis. These cells, called Langerhans' cells, belong to the macrophage lineage and possess the Ia surface molecules essential for sensitization of lymphocytes (*1*, *2*).

Effect of UV Radiation on CHS in the Mouse

In the mouse, CHS can be induced by the application of a contact allergen or a sensitizer, such as TNCB or oxazolone, to the shaved abdominal skin. After 5–7 days, the CHS reaction is elicited in the sensitized animal by application of a dilute solution of the sensitizing agent to both surfaces of the ears or by the intradermal injection of the agent into the rear footpads. The thickness of the ears or feet is measured with a spring-loaded micrometer before the challenge dose of the allergen is applied, and the thickness is measured again 24 hours later. The amount of specific swelling (i.e., ear swelling in sensitized mice minus ear swelling in unsensitized control mice) reflects the degree of edema and cellular infiltrate and hence the magnitude of the immune reaction.

Several years ago, we performed a series of experiments designed to assess the immunologic capabilities of mice exposed repeatedly to UV radiation for the induction of skin cancer. We found that, although many immune responses proceeded normally in these animals, exposure of the mice to UV radiation from unfiltered FS40 sunlamps inhibited a delayed hypersensitivity reaction to DNCB that was injected sc (*3*). More recently, we have shown that a single exposure of the shaved dorsum of BALB/c mice to UV radiation will prevent the subsequent induction of CHS to DNFB or TNCB (*4*). This UV radiation-mediated suppression is systemic, since in our protocol neither the site of sensitization (abdomen) nor the site of elicitation (ears) is directly exposed to UV radiation.

Several conclusions can be drawn from studies of the characteristics of the suppression of CHS by UV radiation: 1) The amount of suppression is directly related to the dose of UV radiation, 2) the amount of suppression is independent of dose fractionation and dose rate over a broad range of conditions, and 3) a minimum of 2–3 days must elapse between the time of UV radiation exposure and application of the contact sensitizer to allow for the manifestation of suppression (*4*, *5*). The cellular basis for this immune suppression has been analyzed in some detail. Lymphoid cell transfer studies by Jessup et al. (*6*) demonstrated that UV irradiation of mice did not alter the responsiveness of their lymphocytes to the sensitizing antigen (DNCB). When lymphoid cells were removed from UV-irradiated mice and used to repopulate lethally X-irradiated recipients, the recipients responded normally to DNCB. This result demonstrated that the impaired response in UV-irradiated mice was not due to altered responsiveness or recognition by lymphocytes but must have been due to an impairment at the level of antigen processing, before lymphocytes were involved in the response, or at the effector portion of the immune reaction that occurs locally at the challenge site. So that these possibilities could be distinguished, lymphocytes from mice immune to DNCB were injected into UV-irradiated animals, and these recipients were tested for their ability to exhibit a CHS response following footpad challenge with DNCB. Since UV-irradiated mice responded as well as unirradiated mice, it was concluded that the afferent portion of the immune response had been affected by UV radiation, probably by altering antigen uptake, processing, or presentation by macrophages or Langerhans' cells.

Direct tests of the antigen-presenting capabilities of macrophages from UV-irradiated mice have been done by Greene and co-workers (*7*). In these studies, the antigen was chemically coupled to glass-adherent spleen cells (predominantly macrophages) from normal or donor mice exposed to UV radiation. These cells were then injected sc into normal or UV-irradiated recipients, and the recipients were tested for CHS. With this approach, it was found that antigen-coupled cells from normal donors could induce CHS in both normal and UV-irradiated recipients. Thus introduction of the antigen bound to a normal antigen-presenting cell bypassed the UV radiation-induced suppression of CHS. This observation strongly suggests that the impairment of CHS by UV radiation is mediated by an alteration in the antigen-presenting cell population in UV-irradiated mice. A second finding from this study was that attempts to immunize UV-irradiated mice with antigen-coupled cells from UV-irradiated donors not only failed to induce CHS but also resulted in the appearance of suppressor cells in the spleens of the recipients. These suppressor cells, shown to be T-lymphocytes, are capable of inhibiting the development of CHS to the coupled antigen when the cells are transferred to a normal recipient.

These results suggest that the failure of UV-irradiated mice to be sensitized after being skin painted with TNCB also might be associated with the production of suppressor T-lymphocytes. Recent experiments have demonstrated that this is indeed the case: UV-irradiated mice painted with TNCB or DNFB fail to develop a CHS reaction to the sensitizing agent but instead develop antigen-specific suppressor T-lymphocytes in their spleens. The induction of these suppressor cells requires both UV radiation exposure and the subsequent application of a contact-sensitizing agent (*5*).

Effects of Various UV Radiation Wavelengths in Suppression of CHS

To determine how UV radiation initiates these changes in immunologic function, we are evaluating the action spectrum for the suppression of CHS. Our preliminary data indicate that the wavelengths most effective in producing suppression are in the region of 260–270 nm. Furthermore, the shape of the action spectrum is consistent with the possibility that DNA may be the photoreceptor, although there are other compounds in skin that have similar absorption spectra (*5*). Because PUVA also damages DNA in skin (although the molecular lesions differ from those induced by UVB radiation) and because PUVA has been shown to be immunosuppressive in other species (*8*), we were interested in determining whether or not PUVA treatment of mice was capable of suppressing CHS systemically. The data presented in table 1 indicate that ip administration of methoxsalen, followed by exposure to radiation from Mylar-

[a] Mice were painted on the shaved abdomen with 100 µl of 5% TNCB or 30 µl of 0.5% DNFB in acetone 5 days after UV radiation treatment. The ear swelling reaction was elicited 6 days later by painting each ear surface with 5 µl of 1% TNCB or 0.2% DNFB, and the amount of swelling was measured 24 hr after application of the challenge dose.

[b] UVB radiation=2.1×10^4 J·m^{-2}; UVA radiation=5.4×10^4 J·m^{-2}; psoralen=0.4 mg methoxsalen administered ip (Kripke ML, Morison WL, Parrish JA: Unpublished data).

filtered Sylvania PUVA bulbs, can indeed reduce the development of CHS in mice. However, it has not yet been determined whether this immunosuppression is mediated by the same cellular pathway as that evoked following UVB radiation exposure, i.e., an alteration in antigen presentation, leading to the induction of T-suppressor cells. Furthermore, there is no firm evidence that the immunosuppression caused by either UVB radiation or PUVA is related to their effects on DNA. Thus the relationship between the immunosuppressive effects of UVB radiation and PUVA remains to be established.

CONCLUSIONS

Regardless of the molecular mechanisms involved, the studies reviewed here demonstrate that in vivo exposure of mice to UV radiation renders them systemically anergic to a subsequent application of a contact-sensitizing agent. Furthermore, this anergy does not represent merely the absence of a response; it also involves the induction of antigen-specific T-suppressor cells. Thus UV radiation exposure of mice changes their immunologic reactivity to contact-sensitizing antigens from a state of positive responsiveness to one of suppression.

It is not yet certain whether this immunosuppressive phenomenon is restricted to contact-sensitizing chemicals applied topically or whether the immune response to some other agents might be altered as well. Previous work has demonstrated that immune responses to histocompatibility antigens and to at least some particulate antigens are unaffected by UV irradiation of the test animal (*3, 9*). However, suppressor cells that inhibit the rejection of highly antigenic UV radiation-induced skin cancers can be found in UV-irradiated mice (*10–12*). Quite possibly, the UV radiation-induced alteration in the presentation of certain antigens is responsible for the induction of these suppressor cells that interfere with tumor immunity. Because these suppressor cells appear to be of considerable importance in the determination of the pathogenesis of UV radiation-induced skin cancers (Fisher MS, Kripke ML: Unpublished data), our current efforts are directed toward testing this hypothesis.

Cell Damage by Near Ultraviolet Radiation: Role of DNA–Protein Cross-links[1,2]

A. Eisenstark,[3] **S. Kovacs,**[3] *and* **J. Terry**[3]

ABSTRACT—Near UV radiation and hydrogen peroxide were found to act synergistically to damage bacteriophage (which contains only DNA and protein) and mammalian cells. DNA–protein cross-links are being considered as the critical molecular alteration that leads to biological damage.—JNCI 1982; 69:177–181.

Forty years ago, Stadler and Uber (*1*) discovered that the action spectrum for mutation in maize could be superimposed on the adsorption spectrum for DNA. However, when compared to the DNA adsorption spectrum, action spectra for inactivation of bacteria (*2*) or phage (*3*) have large deviations in the 300- to 400-nm region (NUV). This observation indicates that DNA is not the sole chromophore for biological damage by NUV radiation. In addition to action spectrum data, considerable evidence shows that the biological effects of NUV radiation are strikingly different from those of FUV radiation (200–300 nm) (*4–7*). As one of many illustrations of NUV and FUV differences, the bacterium *Micrococcus radiodurans* when compared to *Escherichia coli* is notoriously *less* sensitive to FUV radiation but is *more* sensitive than *E. coli* to NUV radiation [(*8*), Caimi P, Eisenstark A: Unpublished observations]. From these and numerous other observations, we conclude that the chromophore for FUV radiation, but not necessarily for NUV, is DNA.

In our research program, we are systematically examining the various biological effects of NUV radiation to identify specific chromophores, targets, molecular alterations, and repair mechanisms (both constitutive and induced). These effects are being tested in different environments (e.g., oxygen, nitrogen, or sensitizing agent).

During our studies, we discovered that tryptophan photoproducts (*9, 10*), especially H_2O_2 (*3, 7, 11, 12*), can act as sensitizers to NUV radiation; this report focuses on this synergistic effect of H_2O_2 and NUV radiation. We have irradiated bacterial cells, bacteriophage, mammalian cells, polypeptides, and amino acids in these studies.

We have been faced with a paradox that has confronted other investigators of NUV radiation; neither DNA nor protein has an absorption peak above 300 nm. Yet many biological effects are seen above the 300-nm wavelength. Even purified transforming DNA (*13*) and purified phage (*3*) can be inactivated by monochromatic NUV radiation above 300 nm.

MATERIALS AND METHODS

This report is derived from several distinct sets of experiments. Reference sources of materials and methods are: *a*) DNA–protein cross-links in phage T7 (*12*) and *b*) cross-links in L929 fibroblasts and B16 melanoma cells (*14*).

RESULTS AND DISCUSSION

DNA–Protein Cross-links via H_2O_2 Plus NUV Radiation Action on Phage T7

We have demonstrated that NUV radiation plus H_2O_2 synergistically inactivates phage T7 by producing DNA–protein cross-links, thus preventing injection of phage DNA into the host (*12*). Also, H_2O_2 enhances NUV radiation lethality and SS DNA breaks in bacteria (*7*), thus providing simple model systems for the study of these synergistic interactions. While action spectrum analysis indicates that synergism for phage is maximal at 340 nm (*4*), the frequency of SS DNA break induction cannot be correlated with the peak of cell killing (*12*); i.e., there is no apparent direct relationship between SS breaks and cell death. Therefore, we searched for other mechanisms of biological damage by H_2O_2 plus NUV radiation and found that the number of DNA–protein cross-links did correlate with the number of inactivated phage (*12*).

To identify cross-links, we appropriately treated double-labeled T7 phages (^{3}H-labeled DNA and ^{14}C-labeled protein) and sedimented them through CsCl block or step gradients (*12*). Alkaline sucrose gradients demonstrated that, while the overall pattern of protein separation was relatively unchanged, the DNA experienced a slight shift with H_2O_2 treatment and a considerable shift with NUV radiation plus H_2O_2 treatment. The fractions showing maximal ^{3}H radioactivity were pooled, dialyzed, and layered on CsCl step gradients. After centrifugation, fractions were collected and counted.

The peak of ^{14}C radioactivity (protein) cosedimenting with ^{3}H radioactivity (DNA) demonstrated a substantial increase in the cosedimentation complex only when phages were treated with both NUV radiation and H_2O_2. These results are most easily explained by DNA–protein cross-linkage induced by NUV radiation plus H_2O_2 treatment of phage T7. This argument is strengthened by the small, but reproducible, decrease in buoyant density of the DNA with NUV radiation plus H_2O_2 treatment (1.687 g/cm^3) versus

that with the control (1.704 g/cm^3), NUV radiation (1.702 g/cm^3), or H_2O_2 (1.701 g/cm^3) treatments. When NUV radiation plus H_2O_2-treated DNA fractions were pooled, dialyzed, digested with DNase I, and subjected to a second round of CsCl centrifugation, the liberated ^{14}C counts banded at about 1.3 g/cm^3, a position characteristic of protein.

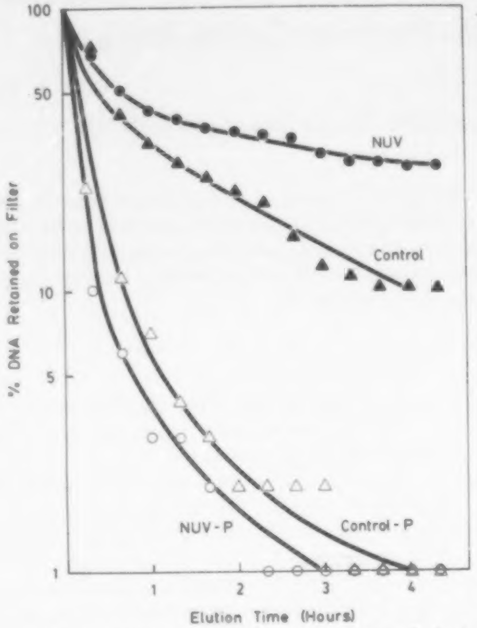
This particular NUV radiation plus H_2O_2 treatment resulted in a surviving fraction of 5.9×10^{-5}, which corresponds to 9.7 lethal hits per phage. (One lethal hit is the dose that yields 37% survival.) Under these conditions, 1.48% of phage protein was cross-linked to DNA or 0.153% per lethal hit. Because the total molecular weight of the protein per phage T7 is 2.4×10^7, the contribution of the molecule (38,000 daltons) of the major head protein is 38,000 (2.4×10^7) or 0.158%.

The close agreement of these two values (0.153% vs. 0.158% theoretical cross-linked protein/lethal hit) suggests that one molecule of phage coat protein (gene 10) could cross-link with DNA per lethal event. Since this protein represents over 60% of the total protein in phage T7, it would be present in sufficient quantities for the juxtaposition necessary for cross-linkage to occur between DNA and protein, particularly since cross-linkage probably has no preferred location with respect to the T7 genome. That the cross-linkage is covalent was suggested by the fact that phages were lysed by either phenol or sodium dodecyl sulfate at high pH, which would have disrupted noncovalent bonds.

STUDIES WITH MAMMALIAN CELLS

In an effort to extrapolate the studies of DNA–protein cross-linking caused by NUV radiation and H_2O_2 to mammalian systems, we conducted experiments on established mouse cell lines, L929 fibroblasts and B16 melanoma cells. We used the DNA alkaline elution technique of Kohn (*14*) and Fornace and Kohn (*15*) for detection of DNA–protein cross-links. Alkaline elutions were run with internal reference cells (L1210 mouse leukemia) to facilitate cross-comparisons between treatments. The percentage of DNA retained on the filter when the L1210 DNA retention was 10% was termed "relative retention." Prior to elution but after treatment, the L929 and B16 cells received 440 rad of X-ray to introduce SS breaks and promote DNA elution by tetrapropylammonium hydroxide–EDTA eluting solution (*15*). The L1210 reference cells received 220 rad of X-ray.

L929 cells were apparently uninfluenced by black-light-bulb NUV radiation in doses between 2×10^5 J·m^{-2} and 6×10^5 J·m^{-2}. A slight replication delay was seen with 8×10^5 J·m^{-2} NUV radiation, but there was no long-term influence on cell cycle time. Irradiations were done with the cells immersed in PBS to obviate irradiated medium artifacts (*16*). A NUV radiation dose of 6×10^5 J·m^{-2} produced detectable DNA–protein cross-links as shown by the high filter retention of the NUV-radiation-treated cellular DNA over that of the control DNA (text-fig. 1). For these experiments, the control cells were incubated in PBS for 4.5 hours, which corresponded to the time that the irradiated cells were in PBS during the NUV radiation exposure. The filter retention was shown to be caused by DNA–protein cross-links (as opposed to DNA-DNA cross-links) because the retention was sensitive to proteinase K digestion (text-fig. 1); whereas the NUV radiation and control curves are quite separate without proteinase K treatment, the curves are nearly coincident after proteinase K treatment. The NUV-radiation-induced DNA–protein cross-links were effectively repaired within 24 hours after treatment as shown by the return of the relative retention to control levels after a 24 hour post-treatment incubation in complete medium (text-fig. 2).



TEXT-FIGURE 1.—Fraction of L929 DNA retained on polyvinyl chloride filters vs. elution time with tetra-propylammonium hydroxide. NUV radiation=6×10^5 J·m^{-2} (black light bulb). *Solid symbols* were elutions run without proteinase K treatment. *Open symbols* and (−P) *designation* were elutions run with proteinase K treatment prior to elution.

To compare NUV-radiation-induced DNA–protein cross-links to chemically induced DNA–protein cross-links, we treated L929 cells with *trans*-Pt, a putative DNA–protein cross-linking agent (*17*). L929 cells were exposed to *trans*-Pt for 1 hour in medium without serum; control cells were incubated for 1 hour in medium without serum and without added *trans*-Pt. Either a 200-μM or a 400-μM concentration of *trans*-Pt caused about a 50% loss of cells within 24 hours of treatment. However, 200 μM of *trans*-Pt-treated cells restored replication capacity by either 4 or 7 days after treatment, whereas 400 μM of *trans*-Pt-treated cells showed no replication capacity by 4 days and only slight replication capacity by 7 days after treatment. DNA alkaline elution data showed that a 400-μM *trans*-Pt treatment produced DNA relative retention that was only slightly higher than that produced by 6×10^5 J·m^{-2} NUV radiation (table 1). The DNA–protein nature of this retention was shown by the considerable loss of retention following proteinase K treatment. However, a 200-μM *trans*-Pt treatment produced DNA relative retention that was essentially the same as that of the controls (table 1).

The NUV radiation effects on B16 survival and replication are contradictory. We have shown and reported an inhibition of replication with a NUV radiation dose as low as 4×10^5 J·m^{-2}; however, at other times the replication data were essentially identical to those obtained with L929, i.e., no extended effects for NUV radiation. The variation in NUV radiation sensitivity seems to be most readily attributable to the variation in pigmentation in these melanoma cells that occurs with extended periods of time in culture (the less pigmented cells being more NUV radiation-sensitive); this aspect is being pursued. The B16 alkaline elution data presented were obtained from cultures that had little pigmentation and therefore exhibited the greatest sensitivity to NUV radiation. NUV radiation (6×10^5 J·m^{-2}) induced DNA–protein cross-links in B16 cells, which as was observed in L929 cells were repaired within 24 hours after treatment (text-fig. 3). Proteinase K treatments confirmed the DNA–protein nature of this NUV radiation-induced DNA retention (data not shown). Thus B16 and L929 cells both exhibit similar DNA–protein damage and repair in response to NUV radiation.

Since NUV radiation plus H_2O_2 treatment has been shown to produce DNA–protein cross-linking in viruses (*12*), we were curious as to whether H_2O_2 might potentiate NUV radiation-induced DNA–protein cross-linking. Both L929 and B16 cells were extremely sensitive to H_2O_2 alone, with B16 showing slightly greater sensitivity. Coincident exposure to NUV radiation (6×10^5 J·m^{-2}) and H_2O_2 (1.5×10^{-4} *M*) did not significantly reduce cell survival. However, NUV radiation plus H_2O_2 did alter the DNA retention by alkaline elution (text-fig. 4). As before, NUV radiation alone showed retention greater than that of the control attributable to DNA–protein cross-links. H_2O_2 treatment alone showed less relative retention than controls; this result was anticipated since H_2O_2 is known to introduce SS breaks in DNA (*18–20*) and the alkaline elution of DNA is known to be accelerated by SS DNA breaks (*21*). The slightly lower retention by H_2O_2-treated B16 as compared to H_2O_2-treated L929 cells may indicate that the greater sensitivity of B16 to H_2O_2 is due to an increase in the number of SS breaks. Following the same reasoning, the even lower retention of NUV radiation plus H_2O_2-treated L929 DNA and B16 DNA may indicate that coincident NUV radiation treatment enhances SS breaking by H_2O_2 rather than increases DNA–protein cross-links.

TABLE 1.—*Relative retention of L929 DNA*[a]

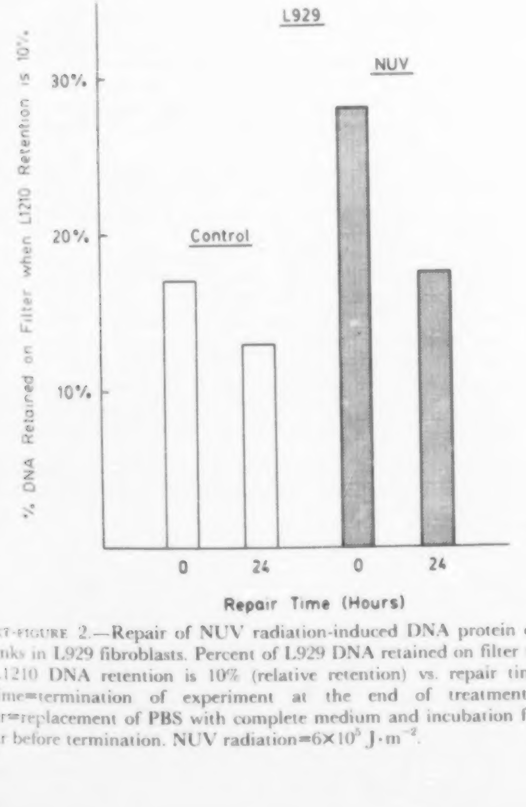
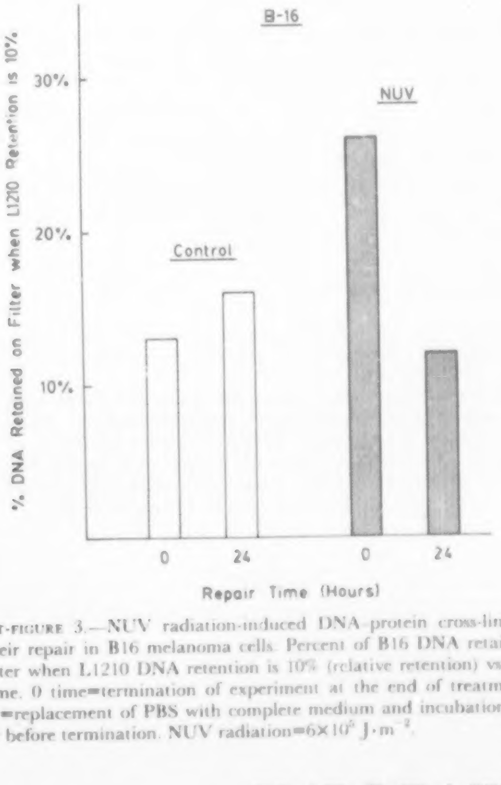
[c] Dose=6×10^5 J·m^{-2}.

[d] Incubation for 4.5 hr in PBS.

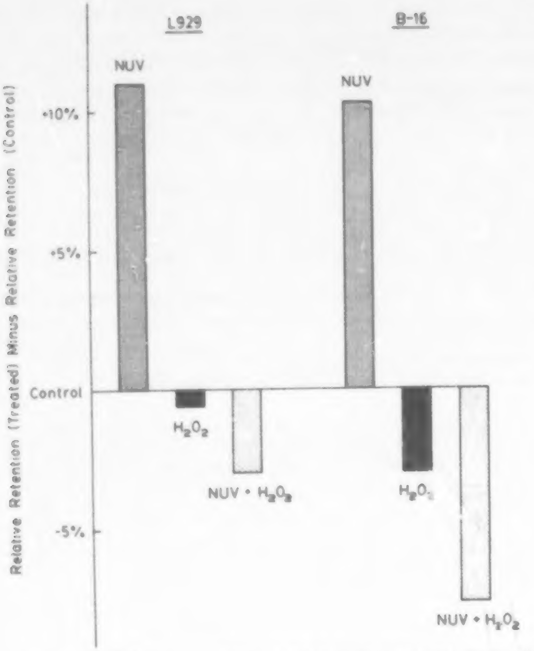
[e] Incubation for 1 hr in RPMI-1640 without serum.



TEXT-FIGURE 2.—Repair of NUV radiation-induced DNA protein cross-links in L929 fibroblasts. Percent of L929 DNA retained on filter when L1210 DNA retention is 10% (relative retention) vs. repair time. 0 time=termination of experiment at the end of treatment. 24 hr=replacement of PBS with complete medium and incubation for 24 hr before termination. NUV radiation=6×10^5 J·m^{-2}.



TEXT-FIGURE 3.—NUV radiation-induced DNA–protein cross-links and their repair in B16 melanoma cells. Percent of B16 DNA retained on filter when L1210 DNA retention is 10% (relative retention) vs. repair time. 0 time=termination of experiment at the end of treatment. 24 hr=replacement of PBS with complete medium and incubation for 24 hr before termination. NUV radiation=6×10^5 J·m^{-2}.



TEXT-FIGURE 4.—Relative retention of DNA from NUV radiation, H_2O_2, and NUV radiation + H_2O_2-treated L929 fibroblasts and B16 melanoma cells. Relative retention (percent DNA retained on filter when L1210 DNA retention is 10%) of treated minus relative retention of control gives the percent of DNA retained above or below control. NUV radiation=6×10^5 J·m^{-2}. H_2O_2=1.5×10^{-4} *M*. All incubations were for 4.5 hr in PBS.

Obviously, phage and mammalian cells respond differently to NUV radiation and H_2O_2 treatments. Whereas a NUV radiation plus H_2O_2 treatment creates DNA–protein cross-links in T7 phage while a NUV radiation treatment alone does not, the reverse seems to be true in mammalian cells. Since the protein "environment" of the DNA in these two systems varies widely, it is not surprising that a strong oxidizing agent like H_2O_2 should differentially alter the potential NUV radiation chromophores.

DISCUSSION

N. Krinsky: I wonder if you would care to comment on the apparent presence of the DNA–protein cross-linking?

A. Eisenstark: We know that some cross-linking will persist in untreated cells. We check this by using still another mouse cell line (L1210) labeled with tritiated thymidine for 2 days. These control cells are always added to irradiated cells labeled with ^{14}C; thus we always do our experiments with two separate cell lines mixed together and we count the double labels. This provides an internal standard. Since the tritiated thymidine is always 5–10%, we choose a specific amount of ^{3}H label to compare with the ^{14}C. Our laboratory, as well as most other laboratories that use this elution technique, has chosen 10% as an internal standard; i.e., when 10% of the tritium remains on the filter, this is the figure that is compared with the ^{14}C-treated cells.

Tumor Virus Induction and Host Cell Capacity Inactivation: Possible In Vitro Tests for Photosensitizing Chemicals[1,2,3]

L. E. Bockstahler,[4] T. P. Coohill,[5] C. D. Lytle,[4] S. P. Moore,[5] J. M. Cantwell,[4] *and* B. J. Schmidt[4,6]

ABSTRACT—The responses of two in vitro mammalian virus-host cell systems to the photosensitizing chemicals proflavine sulfate and 8-methoxypsoralen (8-MOP) in the presence of light are described. Infectious simian virus 40 (SV40) could be induced from SV40-transformed hamster cells by treatment with proflavine plus visible light or 8-MOP plus near UV radiation. The same photosensitizing treatments inactivated the capacity of monkey cells to support the growth of herpes simplex virus. SV40 induction and inactivation of host cell capacity for herpesvirus growth might be useful as screening systems for testing the photosensitizing potential of chemicals. Advantages and disadvantages associated with each system are discussed.—JNCI 1982; 69:183–187.

Photosensitizing chemicals are unique in that exposures to both light and chemical are required for the production of photosensitized reactions. The most common chemically photosensitized reaction that occurs in humans is phototoxicity (*1–4*). The skin and eyes are the organs usually affected. Other reactions that can be induced by photosensitizing chemicals plus light include photoallergy (*1–4*) and photocarcinogenesis (*5*); however, the incidences of these reactions appear to be relatively small. UV or visible light from the sun or artificial light sources can elicit photosensitized reactions. Symptoms associated with chemically photosensitized reactions in humans and other clinical aspects are described elsewhere in these proceedings (*6–9*).

There are numerous known photosensitizing chemicals (*10*), and there is a need for the assessment of the photosensitizing potential of the hundreds of new chemicals placed on the market each year. Information useful for this assessment and for making effective risk-benefit decisions includes results from in vitro biological tests, animal studies, human clinical trials, and epidemiological investigations.

In vitro bacterial and mammalian cell systems for toxicity testing are valuable in that they can be used for large-scale prescreening. They yield relatively quick results and are generally less expensive than animal or human studies. Although numerous in vitro systems are available for chemical carcinogen testing, there has been little involvement in the development and utilization of such systems for the identification of potential photosensitizing chemicals. Examples of short-term tests that have been used for photochemical toxicity testing include the induction of bacterial and mammalian cell lethality, mutagenesis, and DNA-chromosome damage (*3, 11*).

In vitro tumor virus induction (*12, 13*) and inactivation of host cell capacity for virus growth (*14, 15*) are two mammalian virus-host cell systems that have been used extensively to investigate the phototoxic effects of UV radiation. The purpose of this report is to describe the responses of these systems to photosensitizing chemicals plus light. Two well-known chemical-light combinations, proflavine sulfate plus visible light and 8-MOP plus NUV radiation, were selected for photosensitization. The particular induction and capacity systems used were induction of SV40 from SV40-transformed hamster cells and inactivation of the capacity of monkey cells to serve as host cells for growth of herpes simplex virus. The results described suggest that these two systems might be useful as screens for potential photosensitizing chemicals.

TUMOR VIRUS INDUCTION

Several in vitro systems are available for investigating tumor virus induction by DNA-damaging agents (*12*). One of these is the SV40-transformed Syrian hamster kidney cell (clone E) system established by Kaplan et al. (*16*). In this inducible line the entire DNA genome of SV40 is integrated into the host cell DNA. Infectious SV40 can be induced by treatment of the cells with physical or chemical DNA-damaging agents such as UV radiation or mitomycin C (*13, 16*).

Induction of SV40 by photodynamic treatment of SV40-transformed cells with proflavine and visible light is shown in text-figure 1. The clone E line of SV40-transformed hamster cells (*16*) was used. Monolayers of clone E cells were treated with different concentrations of proflavine sulfate, irradiated with broadband radiation from fluorescent lamps (Sylvania "Daylight" fluorescent lamps, 26.7 W·m^{-2}) filtered with plate glass, and incubated (3 days) for virus expression. In addition to visible light, a relatively

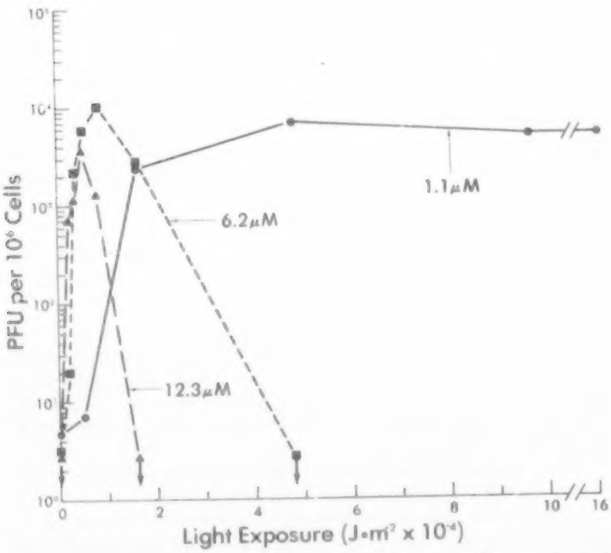
[6] We thank L. D. Hester and L. C. James for help with the capacity studies, O. Ellingson for spectral irradiance measurements, J. C. Kaplan and P. H. Black for gifts of cell stock, and colleagues of the Bureau of Radiological Health for critical review of the manuscript.

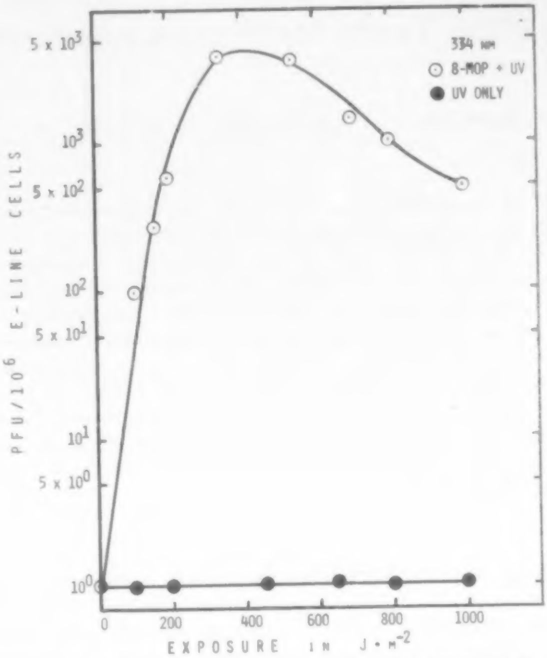
small amount of NUV radiation was present; the plate glass effectively removed wavelengths of UV radiation below 320 nm. The amount of SV40 induced in each sample was determined by the measurement of the SV40 infectivity of cell extracts in permissive CV-1 monkey kidney cells. Further experimental details are given in (*17*, *18*).

The maximum levels of SV40 induced for pretreatment with different proflavine concentrations (text-fig. 1) were similar in amount and represented about a thousandfold increase in virus production above the spontaneous background levels observed with untreated cells. As the concentration of proflavine was increased, less light exposure was needed to reach maximum virus induction. No virus induction above background levels was observed by treatment of the cells with either proflavine or light alone.

Induction of SV40 from clone E cells by treatment with 8-MOP plus NUV radiation is shown in text-figure 2. Monolayers of cells were treated with 0.1 m*M* 8-MOP, irradiated with 334 nm monochromatic NUV radiation, and incubated (4 days) for virus expression. The SV40 infectivity of cell extracts was determined by plaque assay in permissive CV-1 monkey kidney cells. Description of the irradiation system and further experimental details are given in (*15*, *19*). NUV radiation plus 8-MOP gave a maximum induction level of approximately 5×10^3 above the spontaneous background level. Cell treatment with either NUV radiation alone or 8-MOP alone (text-fig. 2) did not induce virus above background levels. Experiments have also been conducted at additional wavelengths in the region 260–365 nm (*19*). 8-MOP was an effective photosensitizer for induction of SV40 at wavelengths tested between 302 and 365 nm. Wavelengths below 302 nm showed no consistently different response to 8-MOP plus UV radiation than to UV radiation alone.



TEXT-FIGURE 1.—Induction of infectious SV40 from SV40-transformed hamster cells after treatment with proflavine plus visible light. Cultures of cells were pretreated with three different concentrations of proflavine sulfate, exposed to visible light, and incubated for virus expression. Induced virus was harvested and assayed for infectivity on permissive monkey cells. The induced virus yield is expressed as the average number of PFU per 10^6 cells. *Each point* represents the average of nine determinations (three separate experiments, in each of which cell extracts from three replicate samples were assayed once). Values lying below 3 PFU are lower than the detection limit of the assay and are indicated by points with *attached arrows*. Data from text-fig. 1B of (*17*) and text-fig. 1 of (*18*) are included.



TEXT-FIGURE 2.—Induction of infectious SV40 from SV40-transformed hamster cells after treatment with 8-MOP plus NUV radiation. Same as text-fig. 1, except that cultures were either treated with 8-MOP (0.1 m*M*) and exposed to 334 nm UV radiation or treated with UV radiation alone. The data represent a typical experiment from (*19*).

The maximum levels of SV40 induced by either of the chemical photosensitization treatments described above were in excess of those observed with 254 nm UV radiation or γ-radiation of cells when the same induction system was utilized (*16*, *19*).

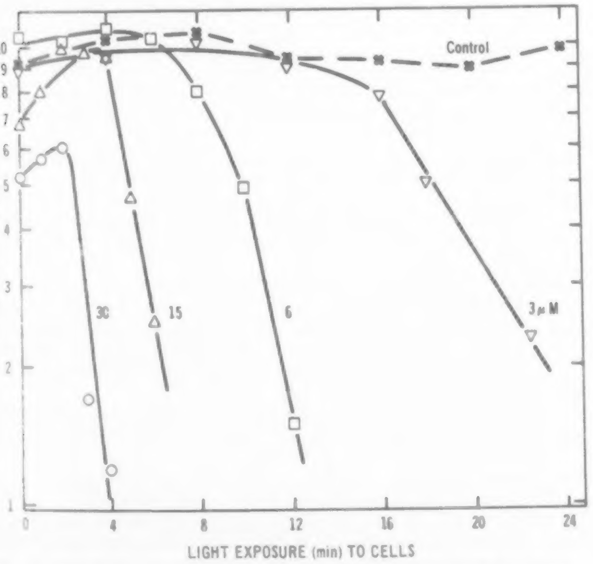
INACTIVATION OF CAPACITY

The ability of a host cell to support virus growth is known as capacity. Inactivation of this cellular function can result from treatment of the cell with DNA-damaging agents. Herpes simplex virus, a DNA-containing human pathogenic virus, is particularly useful for mammalian cell capacity studies because it propagates in a wide variety of mammalian, including human, cells and has a relatively rapid growth cycle. Inactivation of host cell capacity for herpesvirus growth by UV irradiation (*14*, *15*) and by chemical carcinogen treatment (*20*) has been investigated. In this section effects on capacity for herpesvirus growth by chemical photosensitization of host cells are described.

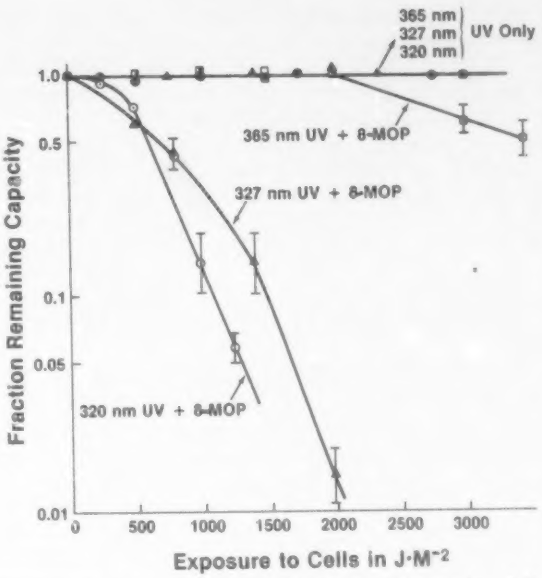
Inactivation of the capacity of CV-1 monkey kidney cells to support herpes simplex virus plaque formation by photodynamic treatment of the cells with proflavine and visible light is shown in text-figure 3. Confluent monolayers of CV-

1 cells were incubated with different concentrations of proflavine sulfate, exposed to broadband radiation from fluorescent lamps (Sylvania "White" fluorescent lamps, 17 W·m^{-2}) filtered with plate glass to remove UV radiation, and infected with herpes simplex virus (type 1). Virus growth was measured by plaque formation (2 days). Further experimental details are given in (*21*). The capacity curves in text-figure 3 are similar in shape to those obtained when the cells are UV irradiated (*15*). Inactivation of capacity was dependent on both light exposure time and dye concentration. A reciprocal relationship between these two variables was suggested from the data. That is, when the dye concentration was doubled, the radiation exposure needed to give a comparable effect was halved. Proflavine concentrations of 15 *μM* and higher in the dark resulted in cellular toxicity, as indicated by lowered plaque formation relative to the plaque formation in the untreated control. Light alone had no effect on plaque formation.

Use of the same capacity system to examine effects of 8-MOP plus NUV radiation is shown in text-figure 4. Confluent monolayers of CV-1 cells were incubated with 8-MOP at a concentration that had no effect on unirradiated monolayers (0.1 m*M*). The 8-MOP-treated monolayers and untreated controls were then treated with three different wavelengths of monochromatic NUV radiation and infected with herpesvirus. Virus growth was measured by plaque formation. Description of the radiation source and further experimental details are given in (*15, 22*). The results demonstrate inactivation of cell capacity for herpesvirus growth by treatment with NUV radiation plus 8-MOP. The exposures required to lower capacity in the presence of 8-MOP were about the same for UV radiation of wavelengths 320 and 327 nm. Little photosensitization due to 8-MOP occurred in the presence of 365 nm of UV radiation. For the wavelengths selected, no effect of UV radiation alone on cell capacity was observed. Further data obtained with this system have verified a wavelength dependence for 8-MOP-sensitized inactivation of capacity by UV radiation in the regions of 320–370 nm (*22*). The shorter wavelengths in this range were more effective than the longer ones. Little difference was observed between the responses of 8-MOP plus UV radiation and UV radiation alone at wavelengths 232-297 nm.



TEXT-FIGURE 3.—Inactivation by proflavine plus visible light of the capacity of monkey cells to support the growth of herpes simplex virus. The light intensity was 17 W·m^{-2}. Concentrations of proflavine were 0 *μM* (X), 3 *μM* (▽), 6 *μM* (□), 15 *μM* (△), and 30 *μM* (○). Virus infection immediately followed photodynamic treatment. Virus growth was measured by plaque formation. The data represent a typical experiment from (*21*).



TEXT-FIGURE 4.—Inactivation by 8-MOP plus NUV radiation of the capacity of monkey cells to support the growth of herpes simplex virus. Cultures of cells were either treated with 8-MOP (0.1 m*M*) and exposed to UV radiation (*open symbols*) or treated with UV radiation alone (*closed symbols*). Wavelengths of UV radiation (in nanometers) are indicated. Virus infection immediately followed UV radiation exposure. Virus growth was measured by plaque formation. *Each curve* represents an average of three or more experiments. The data are from text-fig. 3 of (*22*).

DISCUSSION

The studies reviewed demonstrate the treatment with proflavine plus visible light or 8-MOP plus NUV radiation can inactivate the capacity of monkey cells to support the growth of herpesvirus and can induce SV40 from SV40-transformed hamster cells. Although the mechanisms of tumor induction and host cell capacity inactivation by chemical photosensitization are unknown, DNA damage is likely to be involved. It is known that both of the treatments described can damage DNA (*23, 24*). In general, DNA-damaging agents are efficient inducers of tumor viruses and inactivators of capacity.[7] UV radiation action spectrum studies have shown that DNA is an important target mole-

---

[7] An exception is X-ray treatment, which has relatively little effect on the capacity of monkey cells for herpesvirus growth (*25*).

best copy available

cule for UV radiation effects on both host cell capacity for herpesvirus growth and SV40 induction (*15, 26*). However, other effects of UV radiation and chemical photosensitization are possible including inactivation of RNA, protein, and other cellular constituents (*23, 24*).

The two virus-host cell systems might be useful as tests for potential photosensitizing chemicals. Treatment with microgram quantities of the photosensitizing chemicals in the presence of light gave measurable responses. The reproducibility of results obtainable should be satisfactory for testing purposes. Each procedure permits relatively large-scale testing. One of the tests, capacity inactivation, can be performed with human cells from a variety of different tissues.

As with most in vitro tests for toxicity, these systems have associated disadvantages. For example, virology laboratory experience and facilities would be required. Critical differences between the responses of virus-infected cells and normal cells to chemical photosensitization may exist. For several technical reasons, the virus induction system presently cannot be used with a variety of different host cells. Limited validation of the tests has been made with known photosensitizing and nonphotosensitizing chemicals. It is not known whether the systems would respond to treatments that cause primarily cell membrane damage.

The results described indicate that for screening purposes it would be important to use several different concentrations of chemical, light exposure times, and wavelengths of light. Knowledge of the light absorption spectrum for each chemical would be useful in helping select the appropriate wavelength band of light for irradiation. Use of broadband radiation is recommended so that the absorption bands of different chemicals would be included. The action spectra for clinical drug-induced photosensitivities are usually similar to the absorption spectra for phototoxic reactions and incude higher wavelengths than the absorption spectra for photoallergic reactions (*3*). Most known chemical-induced phototoxic and photoallergic reactions have action spectra in the UV radiation region of the spectrum between 320 and 380 nm (*3*). Little is known about action spectra for chemical photocarcinogenesis.

DISCUSSION

Anonymous: Have you looked at other psoralens as inducing agents, for example, in particular, 5-methoxypsoralen (5-MOP)?

L. E. **Bockstahler:** No, we have not been in the business of examining photosensitizing chemicals very long. We are interested in the different psoralens like 5-MOP. One would expect that 5-MOP would induce SV40. I know that Dr. M. J. Ashwood-Smith has shown that 5-MOP is active in a variety of in vitro test systems, so I would expect that it should give a positive response with our systems.

We are also interested in using some of the furocoumarins that do not make cross-links between the DNA strands, such as angelicin. We need to make sure that nonphotosensitizing chemicals do not give positive responses with our test systems.

E. Riklis: One basic question is that you are taking a target, which is actually viral DNA, and you are inserting this into a cell which has been treated; the viral DNA itself is not pretreated?

Bockstahler: Are you talking about the inactivation of capacity system?

Anonymous: Right.

Bockstahler: That is right. The virus is not treated.

Anonymous: So you are actually treating just the cell with the photosensitizer and not the entire virus-host cell system?

Bockstahler: Yes, When we treat the cells, we believe that DNA is the primary target; however, we have not really shown that. The response we observe might be due, for example, to a membrane effect. We have not really tested this possibility.

Anonymous: Have you tried treating the virus?

Bockstahler: Yes, in separate experiments we have tried treating the virus. For example, in the proflavine experiment, Dr. Lytle carried out separate studies showing that you can inactivate the virus alone by treating with proflavine plus visible light and then infecting.

F. Urbach: Do you get repair of this photodynamic damage to the virus?

Bockstahler: We really have not shown that. We need normal cells and a cell line in which we know that there is no repair of that type of damage—that is, a xeroderma pigmentosum-type-cell—and we do not have that yet.

Comparative Photobiology of Psoralens[1]

M. J. Ashwood-Smith,[2] **A. T. Natarajan,**[3] *and* **G. A. Poulton**[4]

ABSTRACT—The comparative photobiological effects of several furocoumarins [i.e., angelicin, psoralen, 8-methoxypsoralen (8-MOP), and 5-methoxypsoralen (5-MOP)] have been evaluated in a number of biological systems. The photosensitized induced lethality and genetic damage have been assessed in bacterial, animal, and human cells, and the rank order of effectiveness established psoralen as the most active compound followed by 8-MOP, 5-MOP, and angelicin. 5-MOP and 8-MOP are, however, essentially equally active in the production of chromosome damage in human cells in vitro.—JNCI 1982; 69:189–197.

The basic photobiology of furocoumarins has been the subject of two excellent and recent reviews by Song and Tapley (*1*) and by Parsons (*2*). That 8-MOP is a skin carcinogen in mice (*3*) has now been substantiated by a number of workers (*4*). The possibility that 8-MOP is a skin photocarcinogen in humans has been suggested by Stern et al. (*5*) after a careful analysis of the incidence of skin cancer in patients following PUVA therapy for psoriasis. The suggestion that PUVA therapy might prove to be carcinogenic was made by Ashwood-Smith and Grant (*6*) as a result of experimental studies of psoralens with Chinese hamster cells (*7*). Concerns about the safety of 5-MOP (bergaptene), an active ingredient of several suntan preparations, was expressed by Ashwood-Smith (*8*), and preliminary results concerning the photobiology of 5-MOP were published in 1980 (*4*).

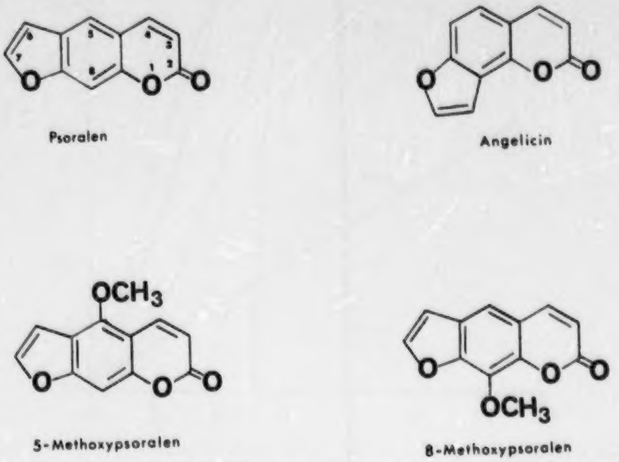
The structure of 5-MOP as well as the structures of psoralen, angelicin, and 8-MOP is shown in text-figure 1. Recent work by Zajdela and Bisagni (*9*) at the Radium Institute in Paris, France, has clearly demonstrated that 5-MOP is almost as potent a skin photocarcinogen in mice as is 8-MOP. This paper presents the results of recent studies on the comparative photobiology of a number of furocoumarins including 5-MOP. The studies presented are joint work conducted in Canada and The Netherlands.

METHODS

Details of irradiation, furocoumarin chemistry, methodology, cell culture, and cytogenetics have been previously presented (*4, 10*).

RESULTS AND DISCUSSION

The relative lethal photosensitizing activities toward bacteria of a series of furocoumarins examined at 40 μg/ml are illustrated in text-figure 2, and the mutation induction (try^- to try^+ for *Escherichia coli* WP2) is shown in text-figure 3. The rank order from the most active furocoumarin to the least was psoralen > 8-MOP > 5-MOP > angelicin for both lethal and mutagenic activities. For dark-induced frame shift mutation (*E. coli* $lac^- \rightarrow lac^+$), however, the rank order was psoralen > angelicin > 8-MOP > 5-MOP.



TEXT-FIGURE 1.—Chemical structures of furocoumarins.

The photosensitized killing of CHO cells in tissue culture is illustrated in text-figure 4. These results were obtained with the use of the standard Puck-type colony survival assays. Neither the UV irradiation nor the furocoumarins per se had any effect on cell survival. Again, at 40 μg/ml, the rank order was psoralen > 8-MOP > 5-MOP > angelicin. The induction of SCE in CHO cells is illustrated in text-figure 5. The responses to 5-MOP and 8-MOP were very similar and were typical. Angelicin (monoadduct formation only) was quite different, which is clearly apparent when SCE were plotted as a function of cell survival (text-fig. 6). Events other than observable damage to chromosomes were related to cellular death from angelicin photosensitization.

The responses of CHO cells to SCE are shown in table 1 in which the data are analyzed by the "unit dose concept"

ABBREVIATIONS USED: AT=ataxia telangiectasia; CHO=Chinese hamster ovary; 5-MOP=5-methoxypsoralen; 8-MOP=8-methoxypsoralen; NUV=near ultraviolet; PUVA=psoralen plus UV radiation (320–400 nm); SCE=sister chromatid exchange(s); UVA=UV, 320–400 nm; XP=xeroderma pigmentosum.

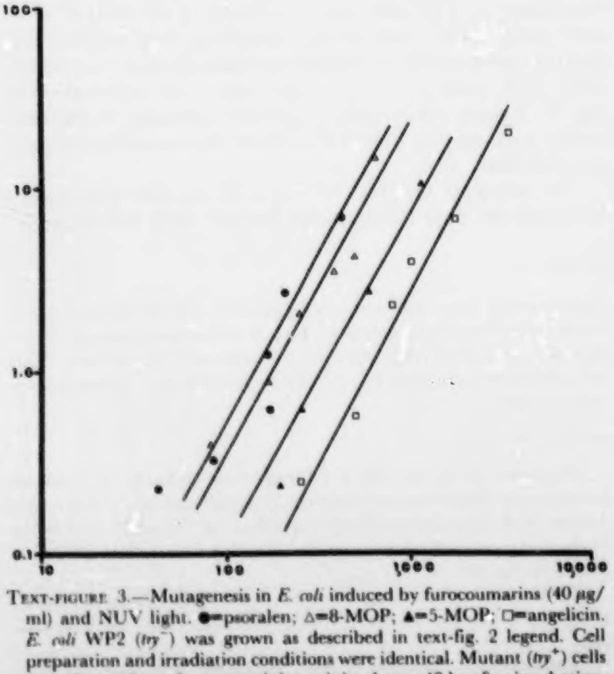
Text-figure 2.—Lethal photosensitization of *E. coli* with various furocoumarins (40 μg/ml each). ●=psoralen; △=8-MOP; ▲=5-MOP; □=angelicin; ○=ethanol control. *E. coli* WP2 (*try*$^-$) was grown in nutrient broth at 22°C, and when bacteria were at a density of ≈5×10^8 cells/ml (logarithmic growth stage), they were filtered and resuspended in 0.07 *M* phosphate buffer at pH 7.2 before being irradiated for 5 min after addition of the furocoumarins. NUV radiation (320–380 nm) was produced by two parallel GEC black lamps (F20T12.BLB) emitting 13.4 J·m^{-2} as measured by chemical actinometry. Cells were plated on nutrient agar and colonies counted after 24 hr of incubation at 37°C. *Ordinate*: survival (%). *Abscissa*: NUV fluence (10^{-2} J·m^{-2}).



Text-figure 3.—Mutagenesis in *E. coli* induced by furocoumarins (40 μg/ml) and NUV light. ●=psoralen; △=8-MOP; ▲=5-MOP; □=angelicin. *E. coli* WP2 (*try*$^-$) was grown as described in text-fig. 2 legend. Cell preparation and irradiation conditions were identical. Mutant (*try*$^+$) cells were detected on plates containing minimal agar 48 hr after incubation. *Ordinate*: log mutants per 10^8 viable cells. *Abscissa*: NUV fluence (log J·m^{-2}).

of Burger and Simons (*11*) which is expressed as [observed SCE per cell/concentration of psoralen (μg/ml)×J·m^{-2}]=*K*, the constant for any given psoralen. 5-MOP and 8-MOP gave values of 1.7×10^{-3} and 2.9×10^{-3}, respectively, while angelicin gave a lower yield of SCE at 5.8×10^{-4}.

The responses of human diploid fibroblasts (foreskin), AT cells, and XP cells to furocoumarins are shown in table 2. With normal cells 5-MOP resulted in 4.5×10^{-3} SCE/unit dose; the value of 8-MOP was 3.7×10^{-3}, and that for angelicin was 8.0×10^{-4}. These values are in surprisingly good agreement with the values obtained with CHO cells. They do, however, indicate that human cells are, in general, more sensitive to furocoumarins than are CHO cells and that 5-MOP and 8-MOP yield essentially the same number of SCE. The responses of AT and XP cells to the formation of SCE are illustrated in text-figure 7 and table 3. The increased sensitivity of AT and XP cells to angelicin is most interesting. Work is presently being done to see if AT heterozygotes are sensitive to angelicin inasmuch as it has been demonstrated that the individuals with AT are more prone to cancer than normal individuals (*12*). Chromosome breaks and exchanges in normal, AT, and XP cells were produced by 5-MOP, 8-MOP, and angelicin (table 3). All three furocoumarins produced considerably more aberrations in AT and XP cells than in normal human cells.

The formation of SCE in human peripheral blood lymphocytes has been reviewed by Burger and Simons (*11*) and is illustrated in table 4.

TABLE 2.—*Induction of SCE in human cells by furocoumarins and UVA radiation*

Furocoumarin[a]	UVA radiation, J·m^{-2}	No. of SCE/cell	No. of SCE/unit dose	Average No. of SCE/unit dose
		Human diploid fibroblasts		
Angelicin	360	10.2	7.0×10^{-4}	8.0×10^{-4}
	600	22.1	9.0×10^{-4}	
5-MOP	60	10.4	4.1×10^{-3}	4.5×10^{-3}
	120	24.4	5.0×10^{-3}	
8-MOP	120	15.7	3.3×10^{-3}	3.7×10^{-3}
	240	40.3	4.2×10^{-3}	
		AT cells		
Angelicin	120	8.0	1.7×10^{-3}	1.7×10^{-3}
5-MOP	36	8.2	5.6×10^{-3}	4.8×10^{-3}
	60	10.4	4.1×10^{-3}	
8-MOP	36	2.8	2.1×10^{-3}	3.1×10^{-3}
	60	8.9	4.1×10^{-3}	
		XP cells		
Angelicin	60	6.3	2.6×10^{-3}	2.3×10^{-3}
	120	9.6	2.1×10^{-3}	
5-MOP	36	7.1	4.9×10^{-3}	5.3×10^{-3}
	60	13.7	5.8×10^{-3}	
8-MOP	36	9.3	6.4×10^{-3}	6.2×10^{-3}
	60	14.4	6.0×10^{-3}	

[a] All furocoumarins were used at a concentration of 40 μg/ml.

TABLE 3.—*Calculated number of chromosomal aberrations (breaks and exchanges) per unit dose*[a]

Furocoumarin	Cell type[b]	UVA radiation dose, J·m^{-2}	No. of aberrations/100 cells	No. of aberrations/unit dose
Angelicin	VH	240	2	0.021×10^{-4}
	AT	240	21	0.21×10^{-4}
	XP	240	28	0.29×10^{-4}
	VH	600	29	0.12×10^{-4}
	AT	600	80	0.33×10^{-4}
	XP	600	124	0.52×10^{-4}
5-MOP	VH	60	3	0.13×10^{-4}
	AT	60	7	0.31×10^{-4}
	XP	60	26	1.12×10^{-4}
	VH	120	35	0.72×10^{-4}
	AT	120	63	1.34×10^{-4}
	XP	120	103	2.12×10^{-4}
8-MOP	VH	120	26	0.52×10^{-4}
	AT	120	134	2.83×10^{-4}
	XP	120	70	1.53×10^{-4}
	VH	240	126	1.33×10^{-4}
	AT	240	256	2.72×10^{-4}
	XP	240	261	2.73×10^{-4}

[a] Numbers were calculated per μg furocoumarin/ml per J·m^{-2} based on data obtained at different NUV doses. Spontaneous and furocoumarin-induced aberrations have been deleted from these calculations.

[b] VH = human foreskin cells.

TABLE 4.—*Induction of SCE in human lymphocytes by 8-MOP and UVA radiation*

Investigator	Concentration, μg/ml	UVA radiation, J·m^{-2}	No. of SCE/unit dose
Carter et al. (*13*)	0.158	7,500	6.9×10^{-3}
	0.158	22,500	6.9×10^{-3}
Waksvik et al. (*14*)	25.0	471	6.5×10^{-4}
	50.0	314	3.0×10^{-4}
Gaynor et al. (*15*)	0.02	9,000	3.1×10^{-2}
	0.10	9,000	1.2×10^{-2}

CONCLUSIONS

Furocoumarins such as 8-MOP and 5-MOP when combined with NUV radiation have lethal, mutagenic, clastogenic, and carcinogenic effects. The unit dose concept of Burger and Simons (*11*) clearly indicates that setting an upper limit of furocoumarin concentration is meaningless inasmuch as a low concentration of furocoumarin and a large dose of light will result in the same degree of genetic damage as a higher concentration of furocoumarin and a smaller dose of UV radiation.

These compounds are very potent monoadduct and DNA cross-linking agents that, when combined with light, have an effect similar to that of alkylating agents and should be so classified.

DISCUSSION

R. Goldemberg: I wish to ask a very simple question. A cosmetic preparation or sunscreen must contain enough 5-MOP to darken the skin. Is the amount necessary for the effect dangerous, for manufacturers of cosmetics and sunscreens are not interested in putting less 5-MOP than is necessary to create this effect? In other words, is there a safe level of 5-MOP in sunscreens and cosmetics?

M. J. Ashwood-Smith: I suppose I shouldn't be answering this question. But I can tell you that one of the legitimate industry objections is that the conditions of human dermal exposure and cellular exposure in vitro are different. 5-MOP or 8-MOP is being added as an alcoholic or acetone—in this case an alcoholic—solution to a cell culture. The reaction of the skin cell can be different when exposed to 5-MOP or 8-MOP in oil in the presence of many other compounds and chemical filtering agents, and the in vitro reaction may not be true in vivo.

I have quantitative information (now being prepared for presentation) that application of one of the suntan preparations to a monolayer of CHO cells followed by exposure to UV light leads to extensive cell death within 2 days. A few remaining cells have a large proportion of chromosome aberrations.

K. Kraemer: I am intrigued by your comments about the response of AT and XP cells to angelicin. Recently, M. C. Paterson and P. J. Smith have shown that cell lines are heterogeneous in their sensitivity to 4-nitroquinoline oxide, although the AT cell lines seem to be equally sensitive to X-rays. Also, use of other agents shows sensitivity differences among different AT cell lines, and it is well known that different XP patients have different degrees of defects. Have you tested more than one XP cell line?

Ashwood-Smith: At the moment, this is being done in Holland.

E. DeFabo: I understand that 5-MOP is a derivative of bergamot oil. Is it a light-induced derivative?

Ashwood-Smith: No, it is a constituent.

DeFabo: It is a constituent of the oil?

Ashwood-Smith: 5-MOP comprises about 0.3% of unpurified bergamot oil. The unpurified oil is commercially available and its 5-MOP content varies. Bergamot oil contained other psoralens. In fact, we have added different concentrations of different psoralens to see if there is interference, which is a possibility. At the moment, the data do not show that there is interference; i.e., there is no synergism, just straight additivity. But the data are scanty at this stage.

L. Freeman: Speaking for those of us interested in the power of in vitro and animal models to predict human responses, I am concerned with the magnitude of the jump you are making and I want to see if I am justified. Certainly, angelicin showed signs of problematic biological activity including, in one case at least, increased lethality. The presumption, I believe, is that it is not a photocarcinogen because it forms a monoadduct. Do you know if that presumption has been tested? If, as I believe, it is not a photocarcinogen, doesn't that raise some doubts about the adequacy of the translation between systems?

Ashwood-Smith: To the best of my knowledge, I am not sure about the assumption that a monoadduct-forming compound is not likely to be dangerous. Angelicin forms monoadducts and not cross-links. There are suggestions that in simple systems cross-links kill and monoadducts give rise to mutations. Therefore, my feeling is that angelicin might turn out to be a photocarcinogen as well if it were properly tested. But it has not been tested.

I can only rest my case on the results of our studies. We showed that angelicin and psoralen caused a lot of chromosome damage. As a result, Elizabeth Grant and I wrote a letter to the *British Medical Journal* suggesting that whatever its benefits, the phototherapy of psoriasis might lead to cancers.

We now all believe that this suggestion is probably valid. We are not certain if psoralens are direct carcinogens, promoters, or affectors of the immune system, or if they exert all three effects. So, I think the extrapolation we made from similar experiments in 1976, which seemed to be only too true, gives some credence to today's extrapolation as well. But I do make the point that, if pigment forms, it may well protect against future skin cancer production. I worry about what happens before the pigment forms and, as you know, that is a subject about which we do not have all the information.

F. Urbach: Have you done the same battery of studies with photodynamic agents, i.e., with anthracene, the dyes, or porphyrin? Do similar things happen with visible light?

Ashwood-Smith: We might have done such a study occasionally, but not deliberately, when we had hemoglobin in the serum.

R. Sayre: Everyone keeps saying how protective pigment really is. It really is not. This morning, a slide was presented that showed that short wavelengths were attenuated in the stratum corneum, longer wavelengths in the epidermis, and only UVA radiation and visible radiation penetrate the dermis.

Let me assure you that you will find some radiation of any wavelength you want to look for passing through the entire epidermis and dermis if you use radiation-detecting equipment that is sensitive enough. The concept that light is stopped by a few cell layers or at a certain skin depth must be wrong; also, the concept that a tan protects us must not be very good when we consider that a fairly dark-skinned person can suffer sunburns when exposed only to four to six times the energy that produces a sunburn in a light-skinned person. The fact that 5-MOP produces a skin pigment does not mean that light will not get through the skin to produce whatever adverse effect we are interested in.

The Food and Drug Administration (FDA) should perhaps be aware that enough adverse evidence is now available to indicate that psoralens should not be purchasable over the counter. Certainly, there is room for them in the bag of medical tricks because they have some very useful properties. But to smear them on people's bodies year in and year out is something else.

Ashwood-Smith: It is often said that CHO cells have a sensitivity that differs from that of human cells. That may be true, and the difference might be a threefold or fourfold one in some instances. I do not know if you noticed, but both in the SCE studies and in the chromosome aberration breakage and deletion studies, furocoumarins, dose for dose and joule for joule, are about three times as effective on human cells as they are in hamster cells. It is my judgment as a photobiologist that in the presence of light, the furocoumarins are, in fact, alkylating agents, and they should be classified as such by the FDA.

C. Zervos: The FDA cannot legally proscribe the use of any material in cosmetic preparations without proof that the material will cause harm. This situation is unlike the case of drugs and food additives in which the law requires premarketing proof of safety.

J. Epstein: Isn't the case about the same with saccharin?

Zervos: Absolutely not. In the case of saccharin, the law requires that the substance be shown to be safe to be marketable; in the case of cosmetic ingredients, there is no such requirement. The burden of proving harm or the potential for harm rests with the Government. In the case of food additives and drugs, the burden of proof of safety rests with the manufacturers.

Epstein: Are we talking about a sunscreen?

Zervos: Yes.

Epstein: Isn't that a medication?

Zervos: Not necessarily.

Epstein: Before we go one step further, I will restate the question I have: How much energy is required to produce a reasonable amount of pigment in a very light-skinned individual using suntanning material containing the usual level of psoralen? A response to this question, which I think is contained in a claim of the protection given the user, is a statement of efficacy. I can't imagine then that the preparation is not a medicine.

Zervos: Someone else from the FDA might wish to comment. I might be wrong, but I do think that the preparation could be a cosmetic.

M. Pathak: Sunscreens are not cosmetics. They alter the function of living cells. Accordingly, the FDA has classified them as topical drugs. Further, although I have been enjoying this discussion about what is safe and what is not and about whether 5-MOP or angelicin—a monofunctional adduct former—is carcinogenic or not, I must suggest that we recognize that any compound which intercalates with DNA as well as forms monoadducts or diadducts—it makes no difference—will be a carcinogen.

Finally, this is 1981. We need not design elegant experiments to get what the FDA requires. A lot of indirect evidence supports what Dr. Ashwood-Smith has been telling us. We have to make and pronounce a judgment. Remember, we are here talking about sick people (patients) as opposed to healthy people at risk. For patients, the physician is intelligent enough to determine what risks and what benefits are appropriate. But if the healthy public is in danger of being exposed to harmful substances such as the furocoumarins, the scientific community, the medical community, as well as the FDA must determine the guidelines of proven safety and whether this or that product should be approved. Thus there really is no question of across-the-board approval or disapproval.

H. Eiermann: I would like to clarify Dr. Zervos' statement. The classification of a product as a cosmetic or a drug depends on the statements made in regard to the product's use and the declarations on the label. More important yet are perceptions of the consumer.

If a product contains a sunscreen and the claim is made, truly or falsely, that it is a suntanning preparation which promotes a healthy tan, the product will be classified as a cosmetic. If the very same product is promoted as a suntanning preparation that screens out UV light and helps prevent sunburning, it would be classified as a drug, most likely an over-the-counter drug, depending on the sunscreen being used.

In the case of 5-MOP, if a statement is made that a product that contains 5-MOP accelerates tanning—which means that it affects the functions of the human body—that product may—and I have to emphasize "may"—be classified as a drug. To my knowledge, no firm decision has yet been made by the FDA; the matter is still under consideration.

If the 5-MOP-containing product is put to, or promoted for, a new use, a new purpose, e.g., to accelerate the tanning process, under the law it could be classified as a new drug, even though 5-MOP has been in use in fragrances for a long time. Under such circumstances, the manufacturer would have to submit to the FDA data and demonstrate safety and effectiveness before the product could be marketed. However, as of now, no firm decision has been made.

Urbach: Having been in many FDA meetings on psoralen and UVA radiation, I am uncertain whether anyone knows just how to classify psoralens. I wish instead to make two additional points.

First, Robert Sayre's statement that pigment doesn't protect the skin is misleading. A recent study by Kaidbey and Kligman showed that pieces of black skin used as a sunscreen provide a skin protection factor (SPF) of about 15, which is almost total protection. Please recall that on Mauna Loa, which is six degrees north of the Equator and 14,000 feet high, the largest insult we have ever measured was 21 minimal erythema doses. So, with 15 SPF protection, even an albino will not get much erythema.

Second and perhaps more important, 7 or 8 years ago when the PUVA business first started, I predicted we were going to find more skin cancers, but my prediction was made for a different reason than most. I wouldn't be at all surprised if we find UVA radiation- and psoralen-induced skin cancer in about another 7 or 8 years, i.e., after 10–15 years from the start of the PUVA therapy. What we are getting now is probably a promotion effect.

Also, not many patients will have been treated for 15 years. Patients get tired of it. It is too expensive, it doesn't work well, and patients have flare-ups; so 6 or 7 years from now, there will not be very many people at full risk, even in the large number of treatment installations.

Much more important than all that I have just said is what I will tell you tomorrow, i.e., that photocarcinogenesis, whether it is induced or augmented by UVB radiation, is described by a dose-response curve. As Harold Blum told me in 1951, if everybody lived long enough, everybody would get skin cancer; i.e., enough of a dose administered enough times presents a real risk provided that the exposed subjects do not die of old age.

The issue with the psoralens is exactly the same. They too produce dose-dependent effects. The question is one of how much. I have no reason to doubt that 5-MOP may be a little less effective in any one of the in vitro tests compared to 8-MOP, and the same may be true even in a usual photocarcinogenesis test.

The question, of course, is how all this information will be used. The really important questions are the following: How much exposure are people going to get, and how much damage are they going to sustain as a consequence? This is basically the point.

I recall I once asked why better instructions were not put in sunscreen packages, e.g., why they did not include instructions telling people to put the sunscreen on in the morning before going out and to use it every day. I was told that the average person who buys sunscreen buys one or two tubes at the beginning of the summer and then buys no more. So the use of sunscreens can't be overwhelming, even though a lot of tubes get sold. People do not really use these things very well.

With a tan you don't need to use anything. A long time ago in an early psoralen conference, we were able to tan people with 20 mg of psoralen/day in the desert. These people acquired a striking protecton against UVB radiation, and the tan lasted more than 6 months.

Pathak: One year.

Urbach: One year of tan with two or three doses of UV light and one or two oral doses of 20 mg of psoralen. If it produces persistent pigmentation that protects—an aspect which needs to be studied because a psoralen-induced tan is different from a UVA radiation-induced tan—it would not be surprising to find that this treatment is a low-risk exposure for the average person but probably not a low-risk exposure for the Celt who is so fair-skinned that he or she hasn't got any melanocytes or pigment anyhow.

The Government can only protect most of the people most of the time, or as the late Dr. Michael Halberstam said: "The Government can protect the innocent, but only God can protect a damned fool from being a damned fool." My point is that although I am in favor of regulating dangerous things, I do not think it should be done in the absence of some information. The information on this particular matter is not in yet. I am not saying it is good or bad, because I do not know. But things should not be condemned out of hand. There is a big difference between giving somebody 60 mg of 8-MOP three times a week along with 20 or even 10 J of UVA radiation year in and year out for years and using a sunscreen, assuming that it produces a tan which lasts a long time and which may or may not provide protection. I think there is a need to consider the dose-response curve of the sunscreen. It is not wise, after all, to dismiss things out of hand. Further, one might ask about that perfume that is full of bergamot oil. The more expensive the perfume is, the more bergamot oil it contains.

S. Zimmerman: I think it is necessary to amplify the notion that the Government tries to protect the people. Some of you have heard the Commissioner talk about the saccharin issue and why saccharin use was not banned after it was found to be a carcinogen. He indicated to a large audience that the decision was not purely scientific. The FDA elucidated the public health risks of saccharin consumption as best as could be done and attempted to take the action called for by the law, i.e., ban its use. It has been stymied there. The FDA can propose to ban the use of saccharin, but in the final analysis, it is the people in Congress and the political pressure groups that can abrogate the power to decide. If they say there are benefits that outweigh the risks, that is the way it is.

For a suntan lotion to be a drug, it must be claimed that it treats some kind of a disease or diseased state; i.e., there must be a claim of a therapeutic effect. Now I can't really see a therapeutic effect in putting a suntan lotion on the skin and getting a tan. There might be other situations in which a disease state could be helped by application of suntan lotion.

F. A. Andersen: Regardless of whether 5-MOP is added to a new drug, to an over-the-counter drug, or to a cosmetic, this basic question needs an answer: What are the risks of human exposure to this chemical? Today's scientific discussion yields, I think, two answers. The first is that there is a potential carcinogenic risk to people who apply this stuff to their skin; the second is that the risks have not been proved yet. I'd like anyone else who has some specific data or specific experience in this area to say yea or nay concerning this particular issue. It is, after all, the substance's actual potential for human carcinogenesis that will determine the ultimate fate of the substance, regardless of its classification.

Zervos: I think I have heard a half-answer to Dr. Andersen's question. There is a clear recognition of a possible carcinogenic danger from using this substance. That is the half-answer. However, there is also this matter of a dose-response function to be considered before discussing other aspects of 5-MOP. There is a need to consider the human cancer risks assumed by those exposed to the substance in suntan lotions.

L. Freeman: I would like to present a bit of additional evidence to that point, evidence that really is not yet finished and is not mine; so I will be very tentative about it.

Let me first return to the issue of classification. I think Mr. Eiermann indicated clearly that, for reasons I do not know if anybody can fully interpret, the problem of the classification of sun products has turned out to be a complex one. The same product can have two different labels and be a cosmetic or a drug accordingly. That is the way it is.

I have a personal bias that there ought to be another kind of a classification for substances which do something but do not treat a disease or a disease condition. There are no provisions for a class of regulated substances different from what we now call cosmetics that do not change the body function substantively and what we now call drugs which do. I wish there were one, and I think we would be better off if cosmetics were regulated that way.

However, the specific issue of the risk has been dealt with and is being dealt with by many people. Dr. Ashwood-Smith attempted to look at his model systems and at the formulations and used a product that contained some sunscreens. I do not know which product he used, but in the hairless mouse, an animal system very similar to that used by Professor Urbach and others, the incidences of tumors, as far as I know, were about the same in animals without protection—i.e., exposed to UV light only—and in animals exposed to sunscreens as well. Further, it is my impression from the work of Dr. Ian Magnus that tumors in exposed animals may be less malignant. However, to even elicit this kind of effect requires studies that have not been properly done.

I believe it is clear from the literature that sunscreens do, in fact, provide some protection against photocarcinogens. If, in fact, psoralens (which are quite ubiquitous) and specifically 5-MOP in sunscreens do not enhance photocarcinogenicity at low dose levels, if there is some enhancement of tanning, and if tanning has some benefit—whether cosmetic or the protection against carcinogenesis—I think we would be very rash to decide that psoralens and specifically 5-MOP are bad given the state of our knowledge.

Finally, if it is decided to call 5-MOP a drug, the following terrible paradox would ensue. Anyone eating a couple of tablespoons of parsley would be getting more 5-MOP than he or she could ever smear on by using sunscreens.

Zervos: The FDA faces such paradoxes day in and day out.

Freeman: The nitrite story is one example showing that, drawn far enough, some of the concepts of regulation are a bit ridiculous. The FDA has now taken the position that it will not forbid the use of nitrite in meat because it does prevent botulism.

Zervos: It is wrong to assume that in its deliberations the FDA does not recognize that, at some time or another, what the law dictates might be at odds with physical reality. Lead is a substance exemplifying the point, nitrite is a similar substance, and caffeine is a similar substance. I can go down a large list.

We are doing a disservice both to the FDA and most importantly to the public if against all indications to the contrary we repeat that the FDA does not recognize these paradoxes. But the law specifies that the Agency has to do certain things, and the Agency tries to abide by the law, to protect the public health to the extent the law provides for, and not to appear silly. The situation is difficult.

Epstein: I think that prevention is a very important aspect of disease control and certainly all here would agree that damage by sunlight will produce disease. Therefore, if it is advertised that some agent will protect the user from sunlight damage, then I would think the agent is a medication by definition.

Eiermann: I wish to make two points to set the record straight and hopefully to clarify a misconception. Classification is a decision that sets the record straight, whether a product is legally a drug or a cosmetic. The classification is strictly a legal matter, and it has implications as to how a product will be handled or regulated by the FDA.

The other point I wish to make is that the FDA does not make the laws. Earlier, the talk was about another product category, one intermediate between drugs and cosmetics. This category actually exists in the minds of the people in the cosmetics industry. They call the products in this category "treatment products." But to establish a category with legal standing would take an act of Congress. The FDA only interprets the law to the best of the ability of the people in the Agency, and classification is nothing else but an interpretation of the law made by Congress. If the law is not interpreted correctly, which is certainly possible, the FDA is taken to court, where it has been known to lose on occasion.

A. Kornhauser: I wish to summarize something regarding 5-MOP and 8-MOP. As far as we know today, both 5-MOP and 8-MOP have more or less similar topical effects. Taken orally, 5-MOP and 8-MOP show very different effects, both in animal models and in people. This had to be taken into account in a risk assessment of sunscreens. Cosmetics are not usually taken orally, but in the context of assessing the relative risks I would ask if there are differences in the potencies of pigmentation induced by 5-MOP and 8-MOP?

Pathak: Both 5-MOP and 8-MOP are melanogenic; i.e., they increase the melanocyte population by a factor of two or three or even five within 72–96 hours. Also, they increase the production of melanosomes and for Caucasians the size of the melanosomes as well. It is not known whether these are the results of somatic mutations or just a follicular contribution. In the hair follicles, the pigment is always large. Thus the changing sizes could represent the follicular hair melanosomes coming up the outer skin layers and contributing to the increased size of melanosome. Beyond that, it has been observed that 5-MOP causes a selective mitosis in melanocytes.

It is still to be determined whether we observed a selective mitosis or we were lucky to get a figure of mitotic melanocytes. But we feel that 5-MOP and 8-MOP have a selective effect on melanocytes, and some studies will have to be done to test this hypothesis.

Zervos: The statement was made, and I think correctly so, that looking at the structures of 5-MOP or 8-MOP one will conclude that each will be a carcinogen in an ultimate test in real animals. Subsequently, the statement was also made that the risk of carcinogenesis in exposed people will depend on the extent of human exposure as well as on the inherent carcinogenicity of the substances.

If today we must regulate these substances according to the degree of risk based on the extent of exposure necessary to obtain a desired effect, how do we go about comparing the relative risks of the different substances or estimating the absolute risks from each of these substances? These are the questions that the FDA must answer now and for some time to come. They are the questions posed by Congress, by the regulated industry, and by the people asked to use the various products. I wish to probe for some answers to these questions.

Urbach: I do not have answers, but I certainly do know that we have a lot of problems in getting an answer for you because of the difficulty of the questions. But let me give you an example with psoralen, although you could use any other agent.

The problem is that in any kind of interaction of a chemical, light, and a living system, any one of these elements can be modified. The chemical can be modified by the light; a lot of photochemistry can happen yielding breakdown products. Concerning the psoralens, i.e., 8-MOP, 5-MOP, or angelicin, whichever one you might select, it will also be a question of the degree of topical or oral exposure and a question of the dose of the administered radiation. Most important, however, a major question will arise with respect to the spectrum of radiation. Completely different effects will be observed with different spectra. The action spectrum for the psoralens does not really peak at 365 nm. It is pretty much a plateau up to 335 nm. At 365 nm, it is dropped by 1 log unit or by one order of magnitude.

Clearly, the results of photocarcinogenesis studies depend on the light source used and on the genetic strains of the test animals. The problem then is a very difficult one for a regulatory agency, and the answers are not easy. Unfortunately, chemical toxicology is not easy.

Again, the problem with light is that three components are present, and each interacts with the others. The immune system can change the host, the light frequently changes the chemical (I am going to spend most of my time tomorrow presenting evidence and data for this phenomenon), and the spectrum of light interacts with all. One can define effects for very specific conditions. The trouble is that when one is dealing with the skin and the sun, the light spectrum of importance absolutely refuses to stand still from one moment to another from one place to another. This is why we do not use the sun as an experimental tool very often. We cannot tell what it is doing.

So, this is a very difficult problem for which I have no immediate answer. Also, I can see that the problem is going to be a lot more complicated than we think.

Ashwood-Smith: I would like to end on a positive note, which has already been partially discussed. A recently improved technique for looking for guanine-resistant peripheral lymphocytes can be applied to individuals badly sunburned and treated with products A, B, and C or no products at all. We could look, for instance, at a population of students who want to get both a good tan and a good grade. We may be able to get an idea as to whether there is a risk in humans. Between 1 and 4% of the peripheral leukocytes are irradiated, so one way or the other mutations in these lymphocytes might be the first direct evidence of the adverse effects of these various psoralen products. Also, these studies may yield information on the mutation rates in normal individuals exposed to the sun under normal circumstances and when exposed to product X, Y, or Z as well.

Genotoxic Effects of Sunlight-Activated Waste Water in Cultured Mammalian Cells[1,2]

Gary F. Strniste,[3] David J. Chen,[3] *and* Richard T. Okinaka[3,4]

ABSTRACT—Cultured Chinese hamster ovary cells were incubated with dilutions of an oil shale retort process water and exposed to natural sunlight. An enhancement of sevenfold to ninefold was seen in photoinduced cytotoxicity (by a colony-forming assay) and mutagenicity [at the hypoxanthine phosphoribosyltransferase (*HPRT*) locus] for cells pretreated with the process water compared to effects seen in cells exposed to sunlight only. Significant photoinduced cytotoxicity was also observed in cultured human skin fibroblasts when exposed to the process water before being exposed to near UV (NUV) radiation. The mutation frequencies (determined for the *HPRT* locus) induced by the process water and NUV radiation were as great as those frequencies seen for far UV light alone. Increases in genotoxicity were observed in excision repair-deficient xeroderma pigmentosum skin fibroblasts when compared to the responses seen in normal cells. Risks to health resulting from the phototransformation of these oil shale retort process waste waters are unassessed at this time.—JNCI 1982; 69:199–203.

As natural petroleum reserves are consumed, it becomes more apparent that the United States will have to supplement its liquid energy supplies with synthetic fuels to meet projected energy demands. Of great promise are the organic reserves locked in vast oil shale deposits located primarily in the western United States. Estimates of hundreds of billions of barrels of economically recoverable crude oil have been made from surveys of oil shale deposits located in Colorado, Utah, and Wyoming (*1*). However, the processes involved in the mining, retorting, upgrading, and refining of oil shale will be accompanied by potential environmental and health-related risks.

One major problem associated with the development of an oil shale industry in this semiarid region will be the utilization of vast quantities of water and the production of process waters, a by-product of retorting which may amount to as much as two barrels of water for every barrel of crude oil produced. Due to its initimate contact with the oil during retorting, process waters, after separation in holding tanks, contain substantial amounts of aqueous-soluble organic materials. These dissolved components most likely contribute to the genotoxic properties of these waters when assessed in the Ames *Salmonella* bioassay (*2*).

For several years, our laboratory has been investigating the process of photoactivation by UV radiation of certain classes of promutagenic–procarcinogenic compounds in an attempt to relate DNA structural damage induced in vitro to the genotoxic effects witnessed in cultured mammalian cell assays (*3–6*). As an extension of this work, we have applied this "photoactivation process" to assess the genotoxic potential existing in by-products of shale oil (*2, 7–10*). This report will consider a particular retort process water and its cytotoxicity and mutagenicity in cultured rodent cells or human skin fibroblasts after activation by UV radiation.

MATERIALS AND METHODS

Test materials.—We have assessed the genotoxic potential of process waters obtained from three retort processes (above ground, modified in situ, and truly in situ) which utilized oil shale from deposits located in the Green River formation in the western United States. Although all waters exhibited photoinduced genotoxic properties (*2, 8, 9*), this report will concern only the most active water, which was obtained from a holding tank for shale oil produced by an above-ground retort. This process water was filtered through Whatman #42 paper and a Millipore 0.2-μm Swinnex unit before use.

Cell cultures.—CHO cells (line AA8-4) were obtained from Dr. L. Thompson (Lawrence Livermore National Laboratory, Livermore, Calif.). This cell line, heterozygous at the adenine phosphoribosyltransferase locus (*11*), was cultured under conditions described elsewhere (*9*). Text-figure 1 outlines the basic scheme for determining the cytotoxic and mutagenic events witnessed in CHO cells. The genetic marker examined in this report is the X-linked, recessive hypoxanthine phosphoribosyltransferase *HPRT* locus. This mutation assay system has been described elsewhere (*9, 12, 13*). Selection for $HPRT^-$ mutants is accomplished by growth of treated cell populations in medium containing 10 *μM* of the toxic base analog 6-TG, after maximal expression period of 8 days' incubation post treatment (*9, 14*). Plating efficiencies of untreated CHO cells are 90–100%.

Cultured human skin fibroblasts were purchased from the American Type Culture Collection (Rockville, Md.). NF (CRL 1295) and XP cells (CRL 1223 or XP12BE) were grown in DMEM containing 20% (vol/vol) FCS (*5*). A similar experimental protocol as diagramed in text-figure 1 for CHO cells was used for the determination of photoin-

duced genotoxicity in human cells, with the following modifications: 1) For toxicity measurements, between 100 and 1,000 cells were plated, and for mutagenicity measurements, 3–6 plates at 10^5 cells/plate were used for each dose tested; 2) the cell attachment period was 20–22 hours; 3) for toxicity measurements, treated plates were incubated a total of 8–11 days with an intermittent feeding on the 5th day; 4) maximal expression of $HPRT^-$ mutants was obtained in 6–8 days (a minimum of four cell divisions); and 5) for selection of $HPRT^-$ mutants, cells were plated at 25×10^3/dish (35–40 dishes/dose) in DMEM with 10% FCS plus 30 μM 6-TG and incubated for 14 days with an intermittent feeding with selection medium on the 7th day. Corresponding EOP determinations were performed at each dose tested. The EOP for untreated NF was 30–40% and for XP cells, 15–25%.

Irradiation.—The source of FUV radiation (primarily 254 nm) was a single 15-W germicidal lamp (G15T8; General Electric Co., Denver, Colo.). The fluence of incident light was 0.5 $J \cdot m^{-2} \cdot sec^{-1}$. The source of NUV radiation (300–400 nm) was a pair of parallel 15-W black lights (F15T8 BLB; General Electric Co.). The incident fluence averaged 6.5 $J \cdot m^{-2} \cdot sec^{-1}$. Calibration of these sources is described elsewhere (*5, 9*). For experiments in which natural sunlight was used as the source of radiation, plates containing attached cells were exposed for various times on the rooftop of the Health Research Laboratory in Los Alamos, N. Mex. (lat. 35°53′11″ N., long. 106°18′58″ W. at an elevation of 7,450 ft above sea level). Sunlight experiments reported here were performed from 12:30 p.m. to 1:30 p.m. during December 1980 and January 1981; the total measured fluence (200- to 2,500-nm wavelength) was 850–950 $J \cdot m^{-2} \cdot sec^{-1}$.

RESULTS AND DISCUSSION

Pretreatment of CHO cells with oil shale retort process waters and subsequent exposure to NUV radiation has resulted in both cytotoxic and mutagenic responses (*2, 8–10*). Mutation frequencies induced at the *HPRT* locus were as great as 50% of those witnessed for the potent skin carcinogen FUV radiation (*9, 10*) at equivalent surviving fractions of cells. However, the magnitude of this genotoxic response was dependent on the process water used; in situ retort process waters were less photoactive than was a corresponding above-ground retort process water. These observations suggested that natural sunlight, which has an NUV component, may have a similar effect.

To test this hypothesis, we exposed CHO cells pretreated with above-ground retort process water (1:270 dilution for 1 hr in the dark) for various times to natural sunlight. The survival data (in terms of colony-forming ability) are shown in text-figure 2. The D_{37} was approximately 50 seconds, whereas untreated CHO cells were inactivated to 37% surviving fraction only after approximately 6 minutes' exposure to sunlight. This represented a sevenfold increase in the photosensitivity of CHO cells pretreated with retort process water as compared to the photosensitivity of untreated cells.

The estimated total solar irradiance (200–2,500 nm) in Los Alamos during December 1980 and January 1981 averaged approximately 900 $J \cdot m^{-2} \cdot sec^{-1}$. Approximately 3% of the solar spectrum is in the NUV range (300- to 400-nm wavelength). Therefore, the fluence of sunlight necessary to reduce survival to 37% for process water-treated CHO cells is 4.5×10^4 $J \cdot m^{-2}$, of which approximately 1,400 $J \cdot m^{-2}$ is NUV. This NUV dose is the same as that obtained in experiments in which NUV radiation was generated by black lights (*9*), indicating the role of this component of the solar spectrum in the photoactivation process.

In text-figure 3, the numbers of $HPRT^-$ mutants (cells resistant to 6-TG) induced by exposure of CHO cells to process water plus sunlight or to sunlight only are plotted versus the percent surviving fraction of cells. At the D_{37} for cell survival, there was a ninefold increase in the number of photoinduced mutants in CHO cells pretreated with process water as compared to untreated cells after subtraction of the natural background mutation frequency (averaged approximately $1/10^5$ cells). As noted for photoinduced cytotoxicity, the frequencies of photoinduced mutations in process water-

treated CHO cells were the same for equivalent fluences of sunlight or black light NUV radiation.

The potential environmental and health-related risks resulting from concomitant exposure to shale oil byproducts (including process waters) and natural or artificial light are unknown. However, a primary target in human exposure will be the skin. We designed the following experiments incorporating cultured human skin fibroblasts as targets to assess better photoinduced genotoxic properties (toward humans) of shale oil retort process waters. As in the CHO cell studies discussed above, only one process water obtained from an above-ground retort facility was used. For comparative purposes, analogous cytotoxic and mutagenic studies were performed with FUV radiation.

In text-figure 4, the survival (colony-forming ability) of NF is shown for NF pretreated with process water and subsequently NUV irradiated or exposed to FUV radiation only. Because of the extreme cytotoxic properties of this water toward cultured fibroblasts, a dilution of 1:700 was necessary to ensure that no cytotoxicity was induced by the process water only (1-hr exposure in the dark). At this dilution, a fluence of NUV of 1,700 J·m^{-2} was necessary to reduce NF survival to 37% that of the control, untreated cultures. Treatment of NF with process water only (1 hr in the dark) or with NUV radiation only (fluences up to 3,000 J·m^{-2}) resulted in no cytotoxicity or mutagenicity.

In text-figure 5, HPRT$^-$ mutants induced in NF by FUV radiation or process water plus NUV radiation are plotted versus radiation fluence. In these experiments, the average background mutation rate (0.3/10^5 cells) was subtracted from each data point. The establishment of conditions maximizing the response of this human cell-HPRT mutation assay has been determined with embryonic human skin fibroblasts (*7, 15*), and those protocols were used in the experiments reported here.

The data in text-figures 4 and 5 are replotted in text-figure 6 to show HPRT$^-$ mutants induced as a function of surviving fraction of cells. These data indicated that the frequency of induction of mutants (per surviving fraction of cells) at the *HPRT* locus was the same after treatment with either FUV radiation or process water plus NUV radiation. At 37% surviving fraction of cells, the number of mutants induced by above-ground retort process water and NUV radiation in NF was about 60% that observed in CHO cells, and the number of FUV radiation-induced mutants in NF was only about 20% that observed for CHO cells exposed to FUV radiation (*9*). These differences in mutation frequen-

TEXT-FIGURE 5.—6-TG^R mutants (HPRT$^-$) induced in cultured NF exposed to FUV radiation (*upper curve*) or oil shale retort process water plus NUV radiation (*lower curve*).

cies observed can be accounted for, at least in part, by differences in repair capabilities in rodent versus human cells (*16, 17*).

In recent studies, we have examined the cytotoxic effects induced in repair-deficient human skin fibroblasts by process water and NUV radiation. XP cells obtained from a patient of complementation group A were used in this study. These cells are extremely sensitive because of deficiencies in their excision repair capacity to FUV radiation and certain classes of chemical compounds (*18, 19*). In text-figure 7 the survival (colony-forming ability) of NF and XP cells pretreated with process water (1:700 dilution) and subsequent exposure to NUV radiation is shown. The inset in text-figure 7 shows the survival of these two cell types exposed to FUV radiation. In both examples, XP cells showed an acute cytotoxic response as compared to the response of NF (fivefold and sixteenfold increases in sensitivity when the comparison is made of the D_{37} values of process water plus NUV radiation treatment or FUV radiation treatment alone, respectively). This result suggests that the magnitude of genotoxicity of photoactivated process water in human cells is influenced by repair capabilities existing in the cell. The decrease in the magnitude of sensitivity seen for XP cells (compared to NF) treated with process water plus NUV radiation versus FUV radiation only could possibly result from a contribution to cell toxicity by non-DNA damage (e.g., membrane damage). We have observed a similar reduction in sensitivity in XP cells (compared to NF) for cytotoxicity induced by photoactivated polycyclic aromatic hydrocarbons (*5*). The role of repair in the modulation of mutagenic potential induced in human cells is the subject of current investigation.

CONCLUSIONS

We reached the following conclusions: 1) Natural sunlight induces a genotoxic response in cultured CHO cells pretreated with oil shale retort process water. 2) The NUV component of the solar spectrum is the apparent radiation responsible for photoactivation. 3) Cultured NF are acutely sensitive to the genotoxic effects of photoactivated process water. The mutagenic potential of photoactivated process

water in human cells is the same as that witnessed for an equivalent killing dose of the potent skin carcinogen FUV radiation. 4) DNA repair processes are involved in modulating genotoxic effects of this photoinduced process. 5) The exact magnitude of the potential health-related and environmental risks resulting from photoactivation of retort process waters and other oil shale byproducts is unassessed at this time. Our demonstration that a significant rate of mutation occurs in cultured human cells exposed to high dilutions of process waters and fluences of NUV radiation comparable to those encountered during nominal exposure to sunlight suggests that such assessment is a prerequisite to the developement of our oil shale resources in a manner that will minimize health-related risks.

Interaction of Oxygen and Oxy-radicals With Carotenoids[1]

Norman I. Krinsky[2] *and* **Susan M. Deneke**[3]

ABSTRACT—Dye-sensitized photo-oxidations of liposomes are inhibited by the presence of carotenoids in the membrane. Some carotenoid bleaching occurs during the reaction. It was shown that carotenoids are capable of inhibiting free-radical-induced lipid peroxidation in liposomes as well as singlet oxygen-induced lipid peroxidation. There is little direct effect of lipid peroxides on carotenoid bleaching during the photo-oxidative reactions. The carotenoid bleaching observed during the dye-photosensitized oxidations of the liposomes appears to be due to interactions between the carotenoid pigments and either radical intermediates from type I reactions or direct chemical reaction with singlet oxygen in a type II reaction. It was concluded that carotenoid pigments function as protective agents by quenching triplet sensitizers, singlet oxygen, and radical intermediates.—JNCI 1982; 69:205–210.

Carotenoid pigments are very widely distributed in nature. They are obligatory components of photosynthetic systems and are also present in many nonphotosynthetic organisms, particularly those that are normally exposed to light in their environment. The basis for carotenoid function in photosynthetic organisms was known to be related to their ability to capture radiant energy and transfer it to the photosynthetic pigments, either chlorophyll in green plants and algae or bacteriocholorphyll in photosynthetic bacteria (*1*), but an adequate explanation for their presence in nonphotosynthetic bacteria was not made available until the observations of Sistrom et al. (*2*) in 1956. These authors concluded that the carotenoid pigments were serving a specific function in protecting the purple sulfur bacterium *Rhodopseudomonas spheroides* from the effects of light, oxygen, and a photosensitizing dye. The harmful effects caused by light, oxygen, and a photosensitizing dye constitute the photodynamic effect, as defined by Blum (*3*). Following the observations of Sistrom et al. (*2*), there were a number of studies that correlated carotenoid presence with protection against photodynamic effects. These studies were done both in photosynthetic (*4, 5*) and in nonphotosynthetic organisms (*6, 7*). Mutant strains of various carotenoid-containing nonphotosynthetic organisms that lacked the ability to synthesize colored carotenoids were found to be sensitive to light in the presence of oxygen and either an exogenous photosensitizer (*6*) or even to endogenous pigments (*7*).

A specific proposal for explaining the mechanism of action of carotenoid pigments in conferring protection against photosensitized oxidation was formulated in 1968 by Foote and Denny (*8*) who demonstrated that carotenoid pigments had the capability of physically quenching singlet oxygen ($^1O_2$) generated during photosensitized reactions. The colored carotenoids are so effective in this process that there have been many conclusions presented in the literature that any protection observed in the presence of carotenoid pigments must be attributed to the presence of $^1O_2$ in the biological system under investigation. The material dealing with carotenoid–$^1O_2$ interactions has been reviewed earlier (*9*), and it is clear that other protective functions can be attributed to carotenoid pigments.

To investigate these processes, we have used the liposome model (*10*) and have demonstrated that carotenoid pigments protect against both photosensitized oxidations (*11*) as well as $^1O_2$ generated by a radio-frequency discharge apparatus (*12*). The liposome model has also been used by a number of investigators (*13–18*) to demonstrate sensitivity to photosensitized oxidations as well as protection by a variety of other compounds, such as vitamin E and cysteamine (*14*).

However, the question still remains whether carotenoid pigments can protect against oxygen-centered radicals or other radical species that can be generated either chemically, photochemically, or radiolytically. In this report, we present evidence that carotenoid pigments not only protect against $^1O_2$ generated during photosensitized oxidations, but also protect against other radical species that have the capacity for oxidizing the unsaturated fatty acids present in membranes and in liposomes.

MATERIALS AND METHODS

Liposomes were prepared by the method of Kinsky et al. (*10*), which utilized egg PC, DCP, and, in some preparations, cholesterol. These liposomes contained trapped glucose. Carotenoids were incorporated into the liposome membranes by inclusion of the desired carotenoid in the original lipid mixture as described previously (*11, 12*). In some preparations synthetic DL-α-phosphatidylcholine, dipalmitoyl (Sigma Chemical Co., St. Louis, Mo.) was used instead of egg PC. When synthetic PC was used all operations were at 50°C rather than at room temperature.

The procedure for toluidine blue O-sensitized photo-oxidations of liposomes has been described (*11*). The suspensions of liposomes containing the dye were illuminated with a Sylvania Sun Gun halogen source ($4.5 \times 10^3\ J \cdot m^{-2} \cdot sec^{-1}$) through a Rohm and Haas amber filter #2422 which removed all wavelengths below 530 nm.

UV radiation was used to initiate liposome oxidations. Samples maintained at 15°C in 10-ml beakers were illuminated from above with five General Electric germicidal

bulbs at a distance of 5 inches. The maximum wavelength of UV emission was 254 nm (in the UVC region which extends from 200 to 280 nm) and the intensity was 4.0×10^3 $J \cdot m^{-2} \cdot sec^{-1}$.

For ferrous ion-induced oxidations, the liposomes were incubated in 0.15 *M* choline chloride at 40°C as described by Leibowitz and Johnson (*19*) with 1 m*M* $FeCl_2$. Controls were incubated in air at 40°C without the added $FeCl_2$.

The extent of liposome peroxidation was determined by the thiobarbituric acid assay for MDA, a lipid peroxide breakdown product (*11*, *20*), as well as by the ferrous thiocyanate assay (*21*). Lysis of the liposomes was measured enzymatically by the release of the trapped glucose or by the loss in turbidity of the suspension as measured by the absorbance decrease at 700 nm (*11*).

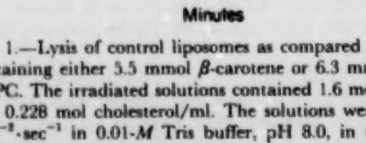
Carotenoid concentrations were measured by extraction of the liposome suspensions with 1 volume of ethanol and 2 volumes of hexane and by measurement of the absorbance of the hexane layer in a Cary model 14 spectrophotometer. Dye concentrations were measured directly in the liposome suspensions.

Crystalline potassium tetraperoxochromate (K_3CrO_8) was obtained according to the procedure of Riesenfeld et al. (*22*).

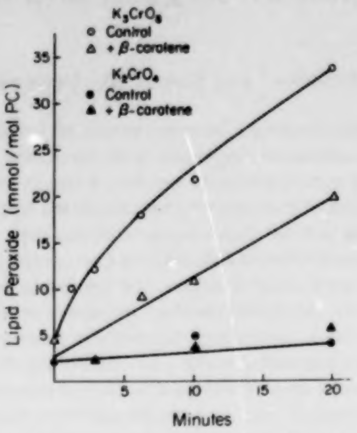
RESULTS

As we have demonstrated earlier, carotenoid pigments such as *β*-carotene or canthaxanthin (4,4′-diketo-*β*-carotene) will prevent the loss of membrane integrity when liposomes are irradiated in air-saturated solutions of photosensitizing dyes such as toluidine blue (*11*, *12*). As shown in text-figure 1, carotenoid pigments are protective agents in this photosensitized system. Other workers have also demonstrated a protection against liposome lysis in irradiated systems by radical quenchers such as vitamin E or cysteamine (*14*).

To help identify the reactive species in this photosensitized system, we investigated the effect of K_3CrO_8 on the liposome preparation. This compound had been used by Hodgson and Fridovich (*23*) to generate $^1O_2$ as well as other oxyradical species. It has also been used by Wörner et al. (*24*) in studying oxidant attack on platelets. As can be seen in text-figure 2, K_3CrO_8 produces a rapid appearance of lipid peroxides which results in liposome lysis. When liposomes prepared with *β*-carotene were exposed to K_3CrO_8, the rate of lipid peroxidation was markedly decreased. Control experiments in which potassium chromate (K_2CrO_4) was used showed no effect of this salt on lipid peroxidation and no effect of the added *β*-carotene. However, the K_3CrO_8 system does not generate solely $^1O_2$ but also apparently results in the formation of the superoxide radical and the hydroxyl radical (*24*). However, it is clear that carotenoids can protect against the product(s) of K_3CrO_8 decomposition.



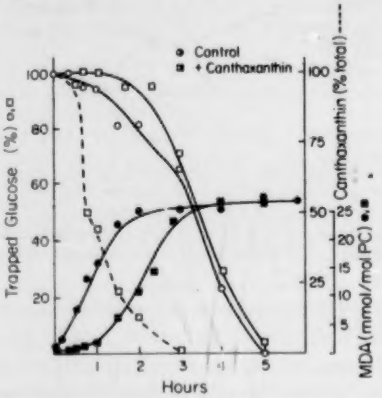
TEXT-FIGURE 1.—Lysis of control liposomes as compared to that of liposomes containing either 5.5 mmol *β*-carotene or 6.3 mmol canthaxanthin/mol PC. The irradiated solutions contained 1.6 mol PC, 0.45 mol DCP, and 0.228 mol cholesterol/ml. The solutions were irradiated at 0.45 $J \cdot cm^{-2} \cdot sec^{-1}$ in 0.01-*M* Tris buffer, pH 8.0, in the presence of 3×10^{-6} *M* toluidine blue at 10°C (*11*).



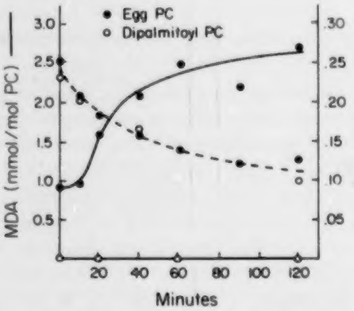
TEXT-FIGURE 2.—Liposomes were prepared as described in text-fig. 1. Either 40 mg of K_3CrO_8 or 40 mg of K_2CrO_4 was added with continuous agitation to 7.5 ml of liposome suspension at 40°C. Aliquots were analyzed for lipid peroxide formation by the ferrous thiocyanate assay (*21*).

UV light has long been known as being capable of initiating lipid peroxidation and starting the chain of radical reactions that leads to the loss of conjugated double bonds among unsaturated fatty acids (*25*). We tested the effect of UV light in our liposomes, prepared with either canthaxanthin or no pigment. The liposomes were exposed to UVC radiation at 254 nm from five germicidal lamps. As can be seen in text-figure 3, the presence of canthaxanthin resulted in a marginal delay in the onset of liposome lysis, as measured by the release of trapped glucose. The effect of the carotenoid pigment on MDA formation was much more pronounced, causing a 1-hour lag period in the appearance of MDA. In addition to measuring liposome lysis and MDA production, we also extracted the total pigment and measured the amount of canthaxanthin present in liposomes. As seen in text-figure 3, canthaxanthin disappeared rapidly with a half-life of approximately 1 hour. The appearance of MDA coincides with the disappearance of the canthaxanthin in the liposomes. Furthermore, lysis, as measured by release of trapped glucose, also seems to coincide with the plateau level of MDA formed in this system.

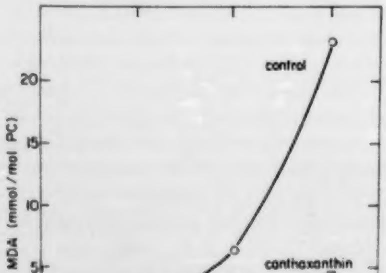
To assess if the bleaching of carotenoid in the UVC-irradiated liposome system was due solely to lipid peroxide formation, we prepared liposomes with either egg PC or synthetic dipalmitoyl PC, the synthetic compound containing only saturated fatty acids. The results of an experiment in which liposomes containing *β*-carotene and either unsaturated or saturated fatty acids were exposed to visible light in the presence of toluidine blue appear in text-figure 4. As can be seen, the production of MDA increased rapidly in the egg PC liposomes after a 10-minute lag period. In contrast, no MDA was observed in the liposomes made from dipalmitoyl PC. Of greater interest is the observation that β-carotene was bleached in both liposome systems at the same rate, indicating that the appearance of lipid peroxide was not required for the induction of bleaching of carotenoid pigments and that this bleaching can occur either through the direct interaction of β-carotene with the triplet sensitizer or by the chemical quenching of $^1O_2$ (*26*).



TEXT-FIGURE 3.—The effects of canthaxanthin on UV-induced lipid damage. Egg PC liposomes prepared with or without canthaxanthin were irradiated with germicidal UV lights (254 nm) at 0.4 J·cm^{-2}·sec^{-1} (*35*).



TEXT-FIGURE 4.—Photosensitized bleaching of β-carotene and formation of MDA in egg PC and in dipalmitoyl PC liposomes. Liposomes were irradiated with white light (>530 nm) at 0.45 J·cm^{-2}·sec^{-1} at pH 8 in the presence of 8×10^{-5} *M* toluidine blue.



TEXT-FIGURE 5.—Fe^{2+}-generated radical oxidation of liposomes. Egg PC liposomes containing β-carotene, canthaxanthin, or no pigment were incubated with 0.1 *M* $FeCl_2$ for varying times, as indicated (*27*).

An additional means of generating radicals involves treating the unsaturated fatty acids with ferrous salts. As shown in text-figure 5, $FeCl_2$ was added to egg PC liposomes containing no carotenoid, β-carotene, or canthaxanthin. Under these circumstances, the incubation of the liposomes with $FeCl_2$ resulted in the appearance of MDA in the carotenoid-free preparation, whereas the liposomes containing carotenoid pigments were protected against radical-induced MDA formation.

DISCUSSION AND SUMMARY

The results of the experiments described here demonstrate clearly that carotenoid pigments are capable of inhibiting membrane lipid oxidations induced by mechanisms other than those involving $^1O_2$. As seen in text-figure 2, carotenoids protect liposomes from the radical species generated during the decomposition of K_3CrO_8. However, these results are still somewhat ambiguous inasmuch as the degradation of this tetraperoxyochromate can give rise not only to $^1O_2$ but also to the superoxide radical and the hydroxyl radical.

The primary products of UV radiation of unsaturated lipids are radicals produced by the expulsion of a hydrogen atom (*25*). These radicals, by reacting with oxygen to form peroxyradicals, can then initiate a chain reaction leading to extensive lipid peroxidation (*28*) and destruction of liposomes (*13, 15, 29*). As seen in text-figure 3, the progress of lipid peroxidation initated by UVC irradiation was significantly delayed in the presence of canthaxanthin. There is some small probability that canthaxanthin may be filtering some of the UVC radiation used for the initiation of lipid peroxidation. However, the absorbance of the carotenoid at this wavelength is very weak in comparison to the absorbance of the unsaturated lipids, and the carotenoid was maintained at a molar ratio of 0.01 of the phospholipid. A relationship was observed between the delay in the appearance of MDA and the destruction of the carotenoid pigment. In the control liposome preparation, MDA production proceeded without a lag period. In contrast, there was a 1-hour lag period in MDA production in the canthaxanthin liposomes, which coincided with the time necessary to bleach 50–60% of the carotenoid pigment. This observation indicates that the carotenoid strongly inhibited the process of lipid peroxidation. The carotenoid pigment was, however, much less effective with respect to maintaining the integrity of the liposome in the UVC-irradiated preparation in comparison to the visible light–photosensitizer preparation (text-fig. 1).

Another effective means for propagating lipid peroxidation consists of treating unsaturated lipids with the ferrous ion, either alone (*19*) or chelated with EDTA (*30*) or ascorbate (*31–33*). Dobretsov et al. (*31*) have suggested that the ferrous ion can accelerate lipid peroxidation reactions by propagating radical chain reactions in the presence of lipid peroxides, as demonstrated by $Fe^{2+} + ROOH \rightarrow Fe^{3+} + RO\cdot + OH^-$ and $Fe^{3+} + ROOH \rightarrow Fe^{2+} + ROO\cdot + H^+$.

In both reactions, the addition of the iron salts generates either alkoxy radicals or peroxyradicals, which continue the process of initiating lipid peroxidation. Also, as seen in text-figure 5, the addition of either β-carotene or canthaxanthin markedly delays the appearance of MDA from liposomes made with polyunsaturated fatty acids and treated with the ferrous ion. Antioxidants such as BHT (*19, 30*) and vitamin E (*32–34*) display a similar inhibition of ferrous ion-induced lipid peroxidation.

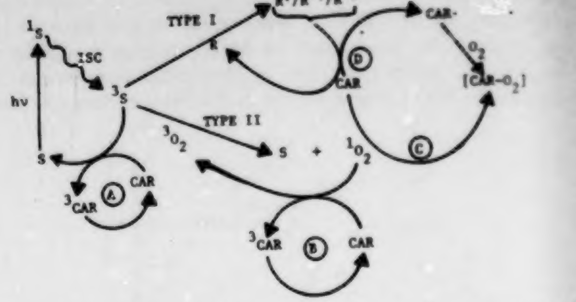
Several likely mechanisms come to mind with respect to the ability of carotenoid pigments to inhibit these free-radical reactions. In one mechanism, the pigments could serve as free-radical quenchers, such as occurs when antioxidants such as vitamin E or BHT are added to a lipid-peroxidizing system. Another possibility is that the carotenoid pigments act as competitive substrates for radical-induced oxidations and therefore delay the onset or propagation of lipid peroxidation until such time as the pigments are consumed in the peroxidative reactions.

In text-figure 4, we demonstrate the effect of fatty acids on the rate of carotenoid bleaching in a photosensitized system in which toluidine blue was the photosensitizer. In this experiment, liposomes were prepared either with normal polyunsaturated fatty acids present in egg PC or with the saturated compound dipalmitoyl PC. As seen in text-figure 4, there was no MDA formation in the liposomes prepared with the saturated fatty acids, whereas there was extensive MDA formation in the liposomes made with unsaturated fatty acids. However, the rate of carotenoid bleaching was the same in both preparations. This observation strongly indicates that factors other than lipid peroxide can have a major impact on the bleaching of carotenoids.

From the work of Foote (*26*), approximately 0.1% of the carotenoid pigments interacting with the $^1O_2$ are known to undergo a chemical reaction resulting in destruction of the pigment. In addition, there is evidence (*35, 36*) that carotenoid pigments can react with the triplet states of excited sensitizers, although it is not at all clear whether this reaction might lead to the bleaching of the carotenoid pigment. There is no question now that the formation of peroxyradicals can have a major impact on carotenoid bleaching, as demonstrated by the work of Packer et al. (*37*).

Packer et al. generated peroxyradicals by pulse radiolysis of CCl_4 in aerobic solutions, which leads to almost instantaneous bleaching of β-carotene. Also, by reaction with peroxyradicals, carotenoid pigments can inhibit the propagation of lipid peroxidation reactions. Such a mechanism may well explain the observations of Kellogg and Fridovich (*38*) who reported that β-carotene inhibited lipid peroxidation induced by xanthine oxidase and acetaldehyde.

We have therefore demonstrated that carotenoid pigments are capable of inhibiting lipid peroxidations induced by factors that lead to radical-mediated reactions other than those initiated by $^1O_2$. There have been other suggestions in the literature that would indicate that carotenoid pigments have a broader effectiveness than that of quenching $^1O_2$. For example, Yamane and Lamola (*39*) suggested that the inhibition of cholesterol-5α-hydroperoxide-induced erythrocyte lysis by β-carotene was due to a radical-quenching reaction on the part of the carotenoid. In addition, Mathews-Roth et al. (*40*) noted that the protective action of a series of carotenoid pigments in a biological system does not necessarily parallel the $^1O_2$-quenching ability of these pigments and suggested that the discrepancy might be due to carotenoids interfering with radical reactions initiated in vivo.



TEXT-FIGURE 6.—Mechanisms of carotenoid protection. Carotenoids (CAR) can quench triplet sensitizers Ⓐ, quench $^1O_2$ Ⓑ, chemically react with $^1O_2$ Ⓒ, or react with radical intermediates Ⓓ. "C" and "D" presumably result in the bleaching of the carotenoid pigment. ISC = intersystem crossing; S = sensitizer; R = an oxidizable substrate.

Clearly, these data show that carotenoids can effectively inhibit lipid oxidation initiated by mechanisms not involving $^1O_2$. The various mechanisms as depicted in text-figure 6 are indicated by *a*) carotenoid quenching of triplet sensitizers, *b*) carotenoid quenching of $^1O_2$, *c*) carotenoid reaction with $^1O_2$, and *d*) carotenoid reaction with radical species.

It is therefore clear that carotenoid pigments are very effective agents in terms of protecting cells against a variety of processes that can lead to cellular damage by several different and distinct mechanisms (*41*). Although the ability of carotenoid pigments to quench $^1O_2$ is an important function with respect to photosensitized oxidations or other reactions which might generate $^1O_2$, the observation of protection in the presence of carotenoids cannot necessarily be interpreted as being due to $^1O_2$ involvement in the process. The radical mechanisms described above would have to be ruled out before one could conclude that the mechanism under investigation indeed involved $^1O_2$. Furthermore, this broad spectrum of protective action exhibited by carotenoid pigments may be related to observations that in the case of some chemically induced mutations (*42*) or UVB-induced mutations (*42–44*), carotenoid pigments have exhibited protective effects. These observations have led to a proposal that carotenoid pigments might function as antitumor agents (*45*). Future experiments should help clarify this hypothesis.

DISCUSSION

L. De Luca: What is the specificity for the carotenoids? In any of these systems, do you get the same effects with retinoids?

N. Krinsky: The specificity with respect to singlet oxygen quenching is very much dependent on the polyene chain length, and there have been very good studies, both in vivo and in vitro, that have demonstrated that you need a minimum of nine conjugated double bonds for the carotenoid to act as an effective singlet oxygen quencher. The effectiveness is related to the triplet energy level of the carotenoid, with respect to the energy difference between singlet excited oxygen and ground-state oxygen.

With respect to triplet sensitization, that is also a function of the chain length of the carotenoid, but it also involves the triplet energy level of the sensitizer. For example, if chlorophyll is used as a sensitizer, one finds that one can use carotenoid pigments with only seven conjugated double bonds as protective agents because the energy level of triplet chlorophyll is lower than that of the energy difference between singlet oxygen and ground-state oxygen.

With respect to radical quenching, that is not at all as clear. One would expect that compounds such as the retinoids could also be readily oxidized by radical species. Under those circumstances, one would expect that retinol or any of the retinoids would also be effective quenchers of radical reactions, although it is not clear at all what might be happening to their radical products themselves.

W. Benson: Could you discuss water-soluble vitamin C as a radical scavenger in this case? It is not a fat-soluble carotenoid.

Krinsky: There is no question that vitamin C is a very effective radical quencher. In fact, if one does experiments in which one has used high-energy radiation to excite biological systems, the major radical species that can be observed after the irradiation turns out to be the radical of vitamin C. So the vitamin C may, in fact, be acting as a sink or a trap for collecting a variety of radicals that are formed within the body and, of course, that would only relate, therefore, to the more water-soluble radicals or those that the vitamin C could, in fact, come into contact with.

Vitamin E, also an effective radical quencher, would be localized, however, within lipophilic areas such as biological membranes and presumably would then be serving as a radical quencher or trap within that particular system.

P. Sundaresan: From the point of view of clinical application, would you suggest that *β*-carotene can be used as a sunscreen?

Krinsky: I will defer that question to the final speaker of the symposium, or do you want it answered now? I do not know very much about sunscreens, but Dr. Mathews-Roth does.

M. Mathews-Roth: As a sunscreen, Dr. M. A. Pathak, Dr. T. B. Fitzpatrick, Dr. E. H. Kass, and I looked at *β*-carotene, and although you get a statistically significant increase in the minimum erythema dose (MED), it is not clinically worth it. So I would have to say that *β*-carotene does not work as a sunscreen.

β-Carotene will be a protective agent against the photosensitization associated with porphyria, and that is what most of my talk tomorrow is going to be about. But we cannot recommend it as a sunscreen. Some people are using it as an artificial tanning agent, as was Man-Tan, but that is strictly for cosmetic purposes.

What we did find is that people who took *β*-carotene tanned a little easier, rather than being burned. But the MED was not significantly increased enough, again, to make it worthwhile. So the answer to your question is really no, you cannot recommend *β*-carotene as a sunscreen.

A Method To Quantify the Potency of Photosensitizers That Modify Cell Membranes[1]

John P. Pooler[2] *and* **Dennis P. Valenzeno**[3]

ABSTRACT—The numerical assessment of sensitizing potency of different species of photosensitizer molecules has historically been impracticable because of the difficulty of measuring all of the factors that must be taken into account. This paper describes a new method for quantifying relative sensitizer potency that obviates most of the past difficulties. The physical data needed to assess photosensitizing potency are the absorption spectrum of a sample of medium containing sensitizer, the illumination spectrum impinging on the preparation, the duration of illumination, and the amount of light-induced modification. The measurement of these quantities is relatively straightforward, but it is easy to overlook a number of artifacts that can distort the values for potency. Avoiding error requires careful attention to the optical properties of the system, particularly in the light path through the medium containing sensitizer.—JNCI 1982; 69:211–215.

Despite more than eight decades of research involving photosensitization of cells, little has been done to quantify the potency of different sensitizers. Review articles and book chapters on photosensitization generally list a handful of compounds as being good sensitizers (e.g., hematoporphyrin, eosin Y, acridine orange, and methylene blue) (*1*, *2*), but quantification is absent. A few reports have given some preliminary estimates of potency for fluorescein sensitizers (*3*, *4*) or porphyrins (*5*), while recent work by us has provided a thorough quantitative comparison of fluorescein sensitizers for photosensitization of nerve cell membranes (*6*) and erythrocytes (*7*). The purpose of this article is to explain the logic behind a general method for the quantification of sensitizer potency. While these ideas are centered on photosensitization of surface membrane function, much of the logic is applicable to modification of any cellular function.

A DILEMMA: HOW TO MEASURE ABSORPTION BY THE MOLECULES ACTUALLY DOING THE SENSITIZING

Reaction 1 outlines the process of membrane photosensitization.

$$\text{Normal membrane function} + \text{photosensitizer} + \text{light} \rightarrow \text{modified membrane function} \qquad [1]$$

In principle any measurable function could be involved in this process (e.g., membrane fluidity, receptor binding capacity, and solute transport rate). The main point is that the function must be quantifiable. Without quantification of the modification, then obviously quantification of sensitizer potency is not possible. Even with reliable quantitation of modification in hand, it is still not easy to derive sensitizer potency because modification also depends on the fluence. And not only is the total energy of light important but also its spectral makeup. The overlap between the illumination spectrum of the light and the absorption spectrum of the sensitizer is as important as total energy. Sensitizer concentration also plays a role. Higher concentrations absorb more photons and lead to greater modification. Just how this factor can be separated from the other factors involved may not be obvious. To sort these things out, one can begin with the photochemical concept of quantum yield (Φ) as given by equation 2. Quantum yield is a measure of potency for a homogeneous mixture of sensitizer and substrate in a reaction vessel.

$$\Phi = \frac{\text{Number of molecules reacted}}{\text{Number of photons absorbed}} \qquad [2]$$

The central concept here is that the amount of light-generated reaction is scaled to the number of photons absorbed. Therefore, any variation in illumination intensity, duration, spectral makeup, sensitizer absorption, and concentration is automatically taken into account. For the modification of cell membranes, unfortunately, one rarely knows which molecules have reacted or how to count them, and a direct assessment of quantum yield is impossible. One can define a potency as given by equation 3.

$$\text{Potency} = \frac{\text{Amount of membrane modification}}{\text{Number of photons absorbed}} \qquad [3]$$

This definition is analogous to that of quantum yield and involves the same essential concept, i.e., scaling modification to the photons absorbed. Even this definition is insufficient to define potency in a practical sense because not all individual sensitizer molecules in a heterogeneous cell membrane system will be equally effective in producing modification. This point is illustrated in text-figure 1. The sensitizer molecules are divided into three classes. Class I is within the membrane, removed from the aqueous environment; class II is adsorbed or bound to the external surface of the membrane; and class III is free in the aqueous environment at various distances from the membrane. A priori, one would expect molecules in class I to have the best chance of photosensitizing modification, whereas those far from the membrane in class III would have no chance. Molecules in class II and nearby ones in class III might have an intermediate chance. If one considers the dimensions of cell membranes, the vast majority of the absorption will occur

---

ABBREVIATION USED: OD=optical density (densities).

---

[1] Presented at the Seventh Food and Drug Administration Science Symposium ("Photochemical Toxicity: Toxic, Allergic, and Carcinogenic Aspects With Emphasis on Predicting Effects in Humans") held at the Uniformed Services University of the Health Sciences, Bethesda, Md., March 16–17, 1981.

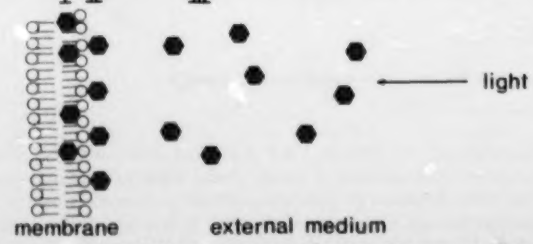
[3] Department of Physiology, University of Kansas, Kansas City, Kans. 66103.

in class III molecules, i.e., those which are not effective in producing modification. Thus in terms of scaling modification to absorption, it appears that one would scale to absorption having nothing to do with the modification. It might therefore seem logical to correct for absorption in the environment and only include absorption by classes I and II, but this method also involves difficulties. Effective sensitization can occur at sensitizer concentrations in the nanomolar range where OD becomes vanishingly small. At higher concentrations, the contribution of molecules at or near the membrane to total measurable absorption is still negligible. Even if the values could be obtained, one does not know the relative contributions to the modification by sensitizer molecules in classes I, II, and nearby regions of III. Thus a dilemma is created. How can one scale modification to absorption by the sensitizer molecules which actually do the sensitizing?

To solve this dilemma we must make the following two assumptions which obviate the need to assess directly absorption by only those molecules doing the sensitizing: 1) The concentration of effective sensitizer molecules is proportional to the concentration in the external medium, and 2) the absorption spectrum of effective sensitizer molecules has the same wavelength dependence as the absorption spectrum of the external medium. Together, these assumptions lead to a third assumption: The number of photons absorbed by effective sensitizer molecules is proportional to the number of photons absorbed in a thin layer of medium. By making this assumption, one can now define potency as modification scaled to absorption in a thin layer of medium. Conceptually, this is like finding the true quantum yield and multiplying it by factors that alter the capture of photons by effective sensitizer molecules relative to those in the bath. As an example, consider two sensitizers with equal concentrations and absorption spectra in the external medium but different concentrations in the effective region. The photon capture in the external medium will be the same for both sensitizers but different in the effective region. The sensitizer with the higher concentration in the effective region will capture more photons there and lead to greater modification. The sensitizer's potency, measured as modification scaled to absorption in the medium, will therefore be higher. In this definition of potency, it makes no difference whether increases in modification are due to more efficient transfer of captured photon energy to a reaction or simply to a greater capture of photons in the effective region—either way this manifests itself as an increase in modification. One utility of this definition is that it permits a simple measurement of medium absorption in a cuvette. Further consideration of the meaning and validity of the assumptions involved is provided later.



TEXT-FIGURE 1.—Location of sensitizer molecules with respect to the membrane. Sensitizer molecules (*solid symbols*) are classified as being within the membrane (class I), adsorbed or bound to the external surface (class II), or free in the external medium (class III).

CALCULATION OF ABSORBED PHOTONS

The energy capture per unit area in an absorbing medium is related to the OD by equation 4, where I and I_o are the transmitted and incident intensities, respectively.

$$I_o - I = I_o(1 - 10^{-\mathrm{OD}}) \qquad [4]$$

One can convert the energy capture to total photon capture by multiplying by illumination time (T), dividing by the energy per photon (hc/λ), and integrating across all wavelengths (equation 5).

$$\text{Absorbed photons} = T\int I_o(1 - 10^{-\mathrm{OD}})\,\frac{\lambda}{hc}\,d\lambda \qquad [5]$$

For low OD, which will always obtain for very short path lengths, the term in parentheses may be simplified according to equation 6.

$$1 - 10^{-\mathrm{OD}} \simeq 2.3\ \mathrm{OD} \qquad [6]$$

Combining equations 5 and 6 and replacing all constant terms by a single constant yield equation 7.

$$\text{Absorbed photons} = \text{constant}\ T\int I_o\mathrm{OD}\lambda d\lambda \qquad [7]$$

The OD at any particular concentration of the sensitizer C can be related to the OD at a standard concentration by equation 8.

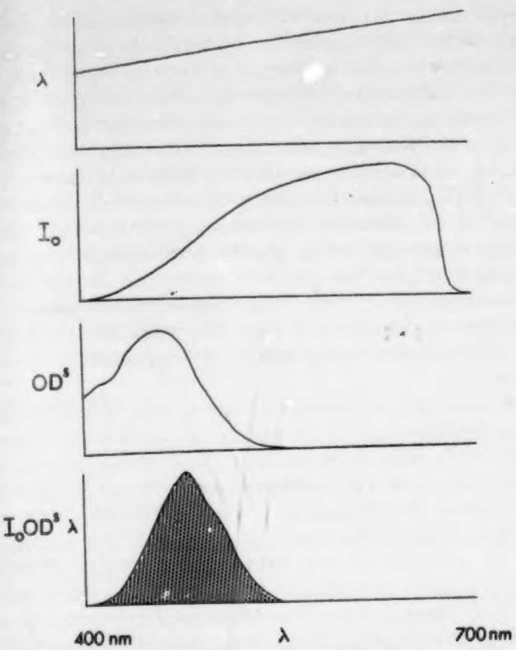
$$\mathrm{OD} = \frac{C}{C^s}\,\mathrm{OD}^s, \qquad [8]$$

where the superscripts refer to the standard condition. Combining equations 7 and 8 gives equation 9.

$$\text{Absorbed photons} = \text{constant}\ T\frac{C}{C^s}\int I_o\mathrm{OD}^s\lambda d\lambda \qquad [9]$$

Equation 9 is a useful expression, for it permits calculation of absorbed photons under a standard condition and then a simple scaling of that result to any particular concentration and illumination time.

Integration of equation 9 is illustrated schematically in text-figure 2. The top three parts of the text-figure show the variation of each of the terms in the integral with wavelength. Wavelength, of course, is linear with itself. The illumination intensity represents a broadband source with a maximum at long wavelengths. The OD is the absorption spectrum of the sensitizer at a standard concentration. The sensitizer shown here absorbs maximally at short wavelengths. The bottom part of the text-figure shows the product of the three factors, which drops to zero at the long wavelength end because the sensitizer no longer absorbs at long wavelengths and drops to zero at the short wavelength end because the source intensity drops to zero there. The shaded area under this curve is the value of the integral. As one would expect, this value varies with intensity of the source, absorption efficiency of the sensitizer, and the degree



TEXT-FIGURE 2.—Wavelength-dependent terms that are integrated to calculate the number of absorbed photons. *Upper three panels* show the wavelength (λ), illumination spectrum (I_o), and the absorption spectrum of the external medium at a standard concentration (OD^s) plotted as a function of wavelength in the visible region. *Bottom panel* shows their product. The area under the product curve (*shaded region*) is the integral of equation 9.

of overlap between the two spectra. Multiplying this area by the other terms in equation 9 then yields the total absorption.

CALCULATION OF RELATIVE POTENCY

The previous section described the process of calculating the number of absorbed photons in an absorbing medium. This logic can be directly applied to the case of a thin layer of medium outside a cell membrane. Call the thickness of this thin layer δ. If the absorption properties of the medium are measured in a typical 1-cm path length cuvette, then the actual absorption will be δ times that value, since OD varies directly with path length. Let D = absorbed photons in a layer of medium δ thick, A = value of the integral in equation 9, M = amount of modification occurring in time T, and P = sensitizer potency.

$$D = \delta \text{ constant } T\frac{C}{C^s}A \qquad [10]$$

$$P = \frac{M}{D} \qquad [11]$$

Equation 11 is now the expression for sensitizer potency which scales modification to the number of absorbed photons in a thin layer of external medium. Although a numerical value for P (potency) may be obtained from this expression, it actually has no meaning without reference to the P-value for another sensitizer, since the units of M and the choice of δ are quite arbitrary. If, however, P for one sensitizer is compared to that for another, then a *relative* potency is obtained—the goal of this whole procedure. Consider now two sensitizers, 1 and 2, for which P-values have been obtained.

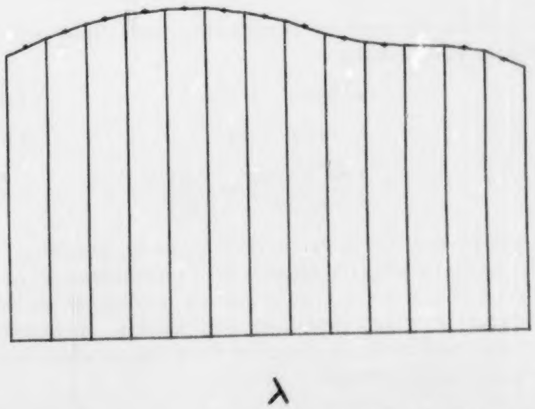
$$\frac{P_2}{P_1} = \frac{M_2D_1}{M_1D_2} \qquad [12]$$

$$\frac{P_2}{P_1} = \frac{M_2T_1(C_1/C_1^s)A_1}{M_1T_2(C_2/C_2^s)A_2} \qquad [13]$$

Equation 13 now expresses the potency of sensitizer 2 relative to that of sensitizer 1. Note that δ and the constants from equation 10 are canceled; therefore, one need not even bother with their values. Once the integral of equation 9 has been evaluated at standard concentrations, then the actual assessment of relative sensitizer potency involves measurement of the amounts of modification, the times of illumination, and the concentrations.

PHYSICAL TECHNIQUES

The assessment of modification is specific for the particular system involved and depends on the function and cell type being photosensitized. Therefore it will not be discussed here. The absorption spectrum of sensitizer is easily measured in a conventional spectrophotometer. The illumination spectrum can be obtained in several ways. One way is to use published spectra of the source employed, modified by any filter characteristics used in the system. Another method is to measure with a spectroradiometer the illumination spectrum impinging on the cell. With fairly broadband sources such as incandescent lamps, either method works reasonably well. One caveat to note here is the problem of screening. The illumination spectrum for this calculation is the spectrum actually reaching the cell membrane, not the spectrum on the outside of a thick layer of concentrated sensitizer. A container of colored sensitizer solution may appear perfectly



TEXT-FIGURE 3.—Division of wavelength-dependent function into small wavelength bands. A portion of the whole curve is shown over a limited region of wavelength. The midpoint within each band is multiplied by the midpoints of the other wavelength-dependent functions at corresponding wavelengths to obtain the points that form the product curve.

transparent, yet it can absorb the vast majority of light at the wavelengths of peak absorption efficiency. For typical sensitizers with a peak molar extinction coefficient of 10^5 and a 1-cm solution thickness, the majority of the light at the absorption maximum will be screened at all concentrations above 3 μM.

Evaluation of the integral of equation 9 is performed numerically. For each of the three terms within the integral, the total wavelength region of interest is divided into small bandwidth sections, as shown in text-figure 3. For each section the midpoints of the relations for each term (I_o, OD, λ) are multiplied together. Plotting these points against wavelength gives the product curve (bottom of text-fig. 2). The products are now summed, and the sum is multiplied by the bandwidth of the wavelength sections, which yields the area (integral of the product curve). While some sort of a digitizer–computer arrangement is very useful to aid in the computation, the process can be done with graph paper and a calculator.

POTENCY BASED ON RATE OF MODIFICATION

For the case of those modifications that proceed as an exponential decline in a function, it is an experimental convenience to base potency on rates of modification.

$$M = F_o(1 - e^{-k_1 t}) \quad [14]$$

$$D = k_2 t \quad [15]$$

Equations 14 and 15 express the amount of modification and absorbed photons during a time t. The k's are rate constants for the processes, and F_o is the value of the modified function before modification begins. For times short enough that M is small relative to F_o, the following approximation holds:

$$M \simeq F_o k_1 t \quad [16]$$

This allows potency to be defined by equation 17.

$$P = \frac{M}{D} = \frac{F_o k_1 t}{k_2 t} = \frac{F_o k_1}{k_2} \quad [17]$$

Now consider the rates of modification and absorption at the start of illumination.

$$(dM/dt)_{t=0} = F_o k_1 \quad [18]$$

$$dD/dt = k_2 \quad [19]$$

$$P = \frac{(dM/dt)_{t=0}}{dD/dt} = \frac{F_o k_1}{k_2} \quad [20]$$

Equation 20 gives the same result as given by equation 17, indicating that scaling the initial rate of modification to rate of absorption yields the same value for potency as scaling the amounts. In many experimental conditions, measuring the rate of modification is more convenient or accurate than measuring a single amount.

COMMENT

The method described here was devised to cope with the apparently hopeless task of assessing sensitizer potency when the information required to define a true quantum yield is absent. While one would like to know the true quantum yield in order to have a better chance of identifying the molecular mechanisms underlying the modification, in a practical sense the concept of potency is more useful. When assessing the relative phototoxicity of a group of compounds, one wants to know how much modification will occur for a given light condition. The physicochemical factors affecting differences in sensitizer permeation and absorption efficiency in the actual region of sensitization are as important as is the true quantum yield in controlling the amount of modification. Ideally, one would like to express potency on a concentration basis, as is done for drugs, but there is no way to bypass the light absorption component of the calculation.

The assumptions underlying these calculations require further comment. It is assumed that modification varies directly with light intensity, sensitizer concentration, and illumination time. For the modification of nerve cell membranes, there is evidence that these conditions hold over fairly large ranges of intensity (*8*) and time.[4] For concentrations of sensitizer up to a range where possible shielding becomes a factor, modification is linear with concentration also (*9*). If there is a nonlinear fluence dependence, as was found for modification of erythrocyte membranes (*10, 11*), then defining a single potency parameter may not be possible. In such a situation, relative potency has to be defined at equivalent fluence for all sensitizers considered, or a new expression for potency must be defined that takes into account the specific fluence dependence.

The second-stated assumption says that the absorption spectra of effective and bath-located molecules have the same wavelength dependence. There is evidence that this assumption is somewhat in error since action spectra for modification of nerve membranes were found to be shifted to longer wavelengths by about 17 nm relative to absorption spectra of the bathing media (*9*). If the illumination spectrum is relatively flat in the region of maximum sensitizer absorption, the resulting error in calculated absorption will be insignificant. If, however, a source is employed with sharp peaks near the absorption maximum, then serious errors in calculated absorption can occur.[5]

Another complication that can confuse the results is a time dependence for distribution of sensitizer. If the arrival of sensitizer molecules at effective sites follows with a delay after the sensitizer is placed in the medium, then measured potency obviously will develop with a delay. For modification of nerve membranes, such a delay is not only significant but also variable from one sensitizer to the next (*6*). Ideally, a preillumination exposure time should be employed allowing a quasi-equilibrium distribution of sensitizer to be reached, or failing this, a standard preillumination time should be chosen for all sensitizers.

In the survey of the history of sensitized cell photomodification, there have been three barriers to the quantification of potency. The first barrier is the dependence of modification on a large number of variables and the difficulty of sorting them out experimentally, or even being aware of them. Overcoming this barrier involves thought about the optics of the system from emission to absorption and the performance of careful control experiments to eliminate unsuspected reasons for variations in potency. The second barrier is a difficulty in quantifying modification. Quantifying modification is a matter of bringing quantitative methods to the field of cell biology. The third barrier has been the subject of this paper—a definition of potency. We hope that these ideas will help future investigators define potency in a meaningful and quantitative way.

---

[4] Unpublished work by us shows that cutting the intensity and increasing the illumination duration by factors of 10 give equivalent modification.

[5] Equivalently, employing a monochrometer or using narrow band-pass filters can cause the same error. Source spectrum in this case means the spectrum actually reaching the effective sensitizer molecules.

DISCUSSION

J. Epstein: Which sensitizers have you rated?

J. P. Pooler: All of our work, as far as actually rating one with respect to the other, has been done with sensitizers of the fluorescein series. We have now done 10 different fluorescein sensitizers.

Anonymous: Are they rated?

Pooler: Yes, they can all be rated. Fluorescein is at the bottom, and rose bengal is at the top. The ratio of their potency is about 30,000 to 1—a huge range.

In Vitro Assay of the Effects of Psoralens Plus Ultraviolet Radiation on Human Lymphoid Cells[1]

Kenneth H. Kraemer, *M.D.*[2,3]

ABSTRACT—An in vitro assay system that mimics some of the features of in vivo oral methoxsalen photochemotherapy (PUVA) in relation to human lymphoid cells was developed. In this assay, suspension cultures of human lymphoid cells were subjected to therapeutic concentrations of 8-MOP and to a UVA radiation spectrum modified to approximate the dermal exposure. The assay permitted correlation and quantitation of multiple 8-MOP plus UVA-induced biological and physical alterations in the same assay system. Thus were demonstrated inhibition of DNA synthesis, reduction of cell survival, production of DNA cross-links, and loss of mixed leukocyte reactivity induced by combinations of 8-MOP and UVA in or near the presumed therapeutic range. This assay may be useful for predicting lymphoid cellular toxicity of other photoactive agents as well as for examining the molecular effects of these agents.—JNCI 1982; 69:219–227.

A new type of clinical therapy, photochemotherapy, explicitly combining photoactive drugs with UV radiation is presently being investigated as a treatment of human diseases. PUVA therapy, the combination of oral 8-MOP plus long-wavelength UVA radiation with wavelengths between 320 and 400 nm, has been found effective in attaining clinical remissions in psoriasis and in the cutaneous lymphoma mycosis fungoides (*1–4*).

In oral 8-MOP photochemotherapy the skin is thought to be the primary treatment target, but circulating lymphoid cells are exposed and may also be affected. Inasmuch as the 8-MOP is taken orally, the drug is present in the blood, and there is a substantial circulation of blood through the dermis. In disease states this circulation may be increased, and leukocytes may leave the skin in considerable numbers and accumulate in the dermis. Short-wavelength UV radiation is absorbed by the epidermis, but long-wavelength UV radiation may penetrate the dermis and thus potentially interact with the psoralen-bathed lymphoid cells.

Oral PUVA treatment has been reported to induce immunologic abnormalities. These abnormalities include diminished cutaneous sensitization with dinitrochlorobenzene (*5*), decreased leukocyte dThd incorporation (*6*, *7*), diminished leukocyte responsiveness to PHA (*7*, *8*) or to $HgCl_2$ (*9*), decreased concentrations of circulating E-rosette-forming T-lymphocytes (*10–12*), and decreased neutrophil concentration (*13*). Increased frequencies of circulating thioguanine-resistant (possibly mutated) lymphocytes have been found in patients (*14*). In vitro UVA radiation exposure of human leukocytes either pretreated with 8-MOP (*7*, *15–21*) or obtained from patients who had received oral 8-MOP (*22*, *23*) resulted in decreased cell turnover, decreased dThd incorporation, diminished PHA responsiveness, and reduced mixed leukocyte culture reactivity.

In the in vitro assay system to be described (*17*, *18*), we have reproduced some of the features of in vivo PUVA therapy. The assay system permits quantitation and simultaneous correlation of multiple biological and physical effects of photochemotherapy on human lymphoid cells. It may be useful in defining the direct actions of drug and radiation and in predicting possible effects in humans receiving such therapy.

CUTANEOUS OPTICS AND CIRCULATORY PHYSIOLOGY

Human skin serves as a filter of UV radiation (*24–26*). The shorter the radiation wavelength, the greater the filtration. This relationship is readily demonstrated if you hold a flashlight against your hand in a darkened room. The flashlight produces visible radiation of approximately 400–700-nm wavelength. The shorter wavelength radiation is blocked, but red light, with a wavelength of about 700 nm, can be seen passing through the entire thickness of skin. This phenomenon is utilized in medicine by pediatricians who transilluminate the crania of infants to diagnose nervous system abnormalities and by otolaryngologists who look for evidence of sinus inflammation.

The stratum corneum is the primary barrier to short-wavelength UV radiation and transmits less than 20% of the radiation below 300 nm (*24*). The entire epidermis, however, transmits about 45% of incident radiation in the UVA region (from 320 to 400 nm) (*24–26*). This UVA radiation may exert direct photobiological effects on dermal structures including blood within capillaries and lymphoid cells (*25*).

Blood flow through the skin has been measured to be about 500 ml/minute (*27*). Since the total blood volume is approximately 5,500 ml, the equivalent of the entire total blood volume circulates through the skin every 11 minutes in an individual at rest. One can formulate a crude estimate of the average dose of UVA radiation that a circulating

[3] *Address reprint requests to* Dr. Kraemer at Building 37, Room 3E24, National Institutes of Health, Bethesda, Md. 20205.

leukocyte would receive (D_L) from skin surface UVA radiation exposure (D_s) by considering the fraction of radiation transmitted by the epidermis (A_e), the treatment time (T), the rate of cutaneous blood flow (R), the number of circuits (n) a cell would make during the treatment time, the volume of blood in the body (V_b), and the volume of blood in the dermis (V_d).

Let p represent the fraction of the surface dose received by a leukocyte. Then

$$D_L = pD_s. \qquad [1]$$

Now

$$D_s = F_s \times T, \qquad [2]$$

where F_s is the fluence at the skin surface.

If F_d is the fluence in the dermis and t_L is the time a leukocyte spends in the dermis per circuit, then

$$D_L = F_d \times t_L \times n. \qquad [3]$$

Now

$$R = V_d/t_L = V_b/t_b, \qquad [4]$$

where t_b is the time for the total blood volume to pass through the dermis. This formula may be rearranged to

$$t_L/t_b = V_d/V_b. \qquad [4a]$$

But

$$n = T/t_b. \qquad [5]$$

Also,

$$F_d = A_e \times F_s. \qquad [6]$$

Thus $p = D_L/D_s = (F_d \times t_L \times n)/(F_s \times T) = (A_e \times F_s \times t_L \times T/t_b)/(F_s \times T) = A_e \times t_L/t_b$. Hence

$$p = A_e \times V_d/V_b. \qquad [7]$$

Equation 7 indicates that the fraction of the surface dose received by a circulating leukocyte is equal to the fraction of radiation transmitted by the epidermis times the ratio of the dermal blood volume to the total body blood volume. The epidermis transmits about 45% of the UVA radiation (A_e) (*24–26*), and the total blood volume (V_b) is about 5,500 ml (*6*, *17*, *27*). From these considerations, it is apparent that the crucial unmeasured component in determining the extent of UVA radiation exposure to leukocytes is the cutaneous blood volume. The flow rate is of secondary importance inasmuch as increases in flow rate resulting in less exposure per circuit are compensated for by more circuits during the period of exposure. I have been unable to find reliable estimates of human cutaneous blood volume. Data have been published for rodents and range from 20 to 70 µl blood/g of skin (*17*). If one assumes a human cutaneous blood volume of 100–500 ml (representing 50–250 µl/g skin), then circulating leukocytes would receive approximately $p = (0.45 \times 100\text{–}500\ \text{ml})/5{,}500\ \text{ml} = 0.8\text{–}4\%$ of the skin surface dose. Thus with a typical human skin surface exposure of 10,000 $\text{J} \cdot \text{m}^{-2}$ during photochemotherapy from a source delivering 100 $\text{J} \cdot \text{m}^{-2} \cdot \text{sec}^{-1}$, each lymphocyte would be estimated to receive 800–4,000 $\text{J} \cdot \text{m}^{-2}$ UVA radiation.

SERUM PSORALEN CONCENTRATIONS

Several methods have been described for the measurement of serum 8-MOP concentrations (table 1). The methods include TLC (*28–32*), GC (*35–39*), GLC (*34*, *40*, *41*), HPLC (*41–46*), and a bacterial bioassay (*47*). The standard dose of 8-MOP in PUVA therapy is about 0.6 mg/kg. Peak levels of 8-MOP have generally been found 2 hours after drug ingestion; however, variation is considerable among patients. Detectable peak levels have been reported to vary widely among patients; the range is from a low of 0.002 µg/ml to a high of 4 µg/ml. Some of this variation may be due to variations in drug composition or absorption (*37*, *45*). However, even a single laboratory reports hundredfold differences in peak values among patients. Most laboratories found peak values between 0.1 and 1.0 µg/ml. Since 8-MOP is metabolized by hepatic enzymes, some of the reported values may include circulating metabolites. The possible effects of these metabolites have not been thoroughly investigated.

IN VITRO ASSAY SYSTEM

Human lymphoid cells were chosen for use in the in vitro assay (*17–21*). Primary cultures containing large numbers of lymphocytes were obtained by leukophoresis of normal donors and were further purified by flotation in lymphocyte separation medium. Lymphocytes could be maintained in short-term culture in RPMI-1640 medium supplemented with 17% fetal calf serum. This procedure resulted in a mild blastogenic response to the calf serum. These cells were used for short-term assessment of DNA synthesis. Smaller numbers of fresh leukocytes obtained by differential centrifugation of heparinized blood were used for the examination of immune reactivity.

For long-term cultures, Epstein-Barr virus-transformed lymphoblastoid cells were utilized from normal donors. These cells grow indefinitely in suspension in the culture medium. Their use permitted assessment of long-term cellular effects such as survival after treatment. We grew large numbers of the lymphoblastoid cells rapidly to facilitate measures of physical parameters such as DNA cross-linking.

The cells were exposed to radiation from the same type of lamp as that used for PUVA therapy. Our measurements of the spectrum of this lamp (*17*, *18*) are shown in text-figure 1. Spectral irradiance on a $\log_{10}$ scale was plotted versus the wavelength. The peak energy of the unfiltered lamp was at 355–365 nm, and 98% of the measured UV radiation output was in the UVA region between 320 and 400 nm. Approximately 2% of the radiation from the unfiltered lamp was between 280 and 320 nm in the UVB region. This UVB radiation is known to be more active biologically than UVA radiation is, but UVB radiation is filtered out by the epidermis (*24–26*). Thus we used 6-mm-thick plate glass to filter out the UVB radiation. Text-figure 1 also shows the measured output through the plate glass filter. There was virtually no emission below 320 nm. Also shown in text-figure 1 is a calculation of the predicted spectral irradiance with the use of pigmented or unpigmented human epidermis as a filter to mimic the filtering effect of the epidermis on

TABLE 1.—*8-MOP therapeutic blood levels*

Assay method	No. of patients	8-MOP dose	Peak value: Range, μg/ml	Peak value: Time,[a] hr	Reference
TLC	9	0.6–0.7 mg/kg	0.15–4.58	2–6	(*28*)
TLC	37	0.6–0.7 mg/kg	0.01–0.93	ND	(*29*)

[a] ND=not determined (value listed was measured 2 hr after ingestion).

radiation impinging upon lymphocytes in the dermis. The plate glass partially mimics this filtering effect.

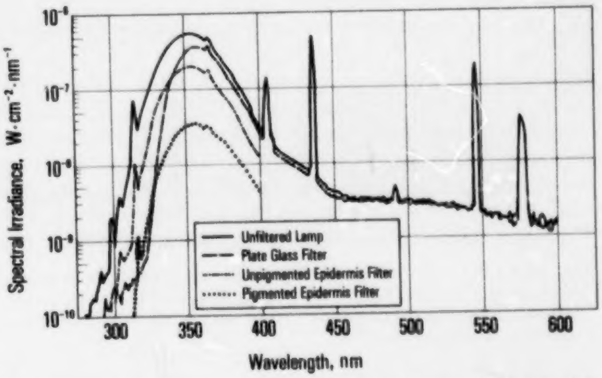
Cells were irradiated at 37°C from beneath the flasks (fig. 1). We suspended the cells in a UVA radiation-transmitting salt solution to minimize possible UV interactions with medium components and thereby to measure direct photochemical effects. The cells were kept in suspension and were exposed to different portions of the field during the time of irradiation by the plate glass being shaken at approximately 40 rpm.

8-MOP was added to the cells before the UVA radiation exposure. All manipulations were performed with gold fluorescent lamp illumination.

MEASUREMENTS OF DNA SYNTHESIS AFTER 8-MOP PLUS UVA TREATMENT

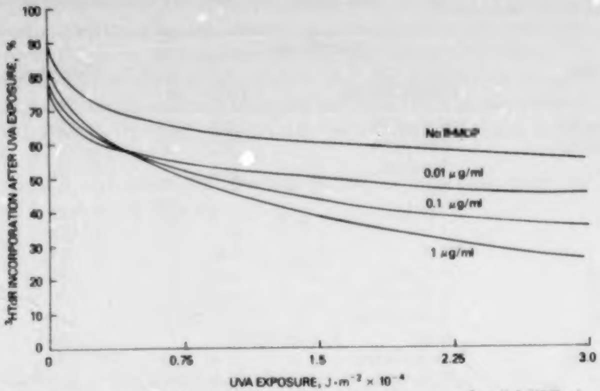
DNA synthesis was determined in a filter assay by the measurement of [^{3}H]dThd incorporation by the lymphoid cells during the first 2 hours after treatment (text-fig. 2). A dose-dependent decrease in DNA synthesis was apparent in primary lymphocyte cultures after exposure to UVA radiation in the absence of 8-MOP. Pretreatment with 8-MOP before UVA radiation exposure resulted in an additional decrease in DNA synthesis.

We had previously studied DNA synthesis in leukocytes of psoriasis patients receiving PUVA (*6*) by measuring [^{3}H]dThd incorporation in unstimulated leukocytes obtained immediately before and after UVA radiation treatment (text-fig. 3). The extent of the decrease in leukocyte DNA synthesis observed in vitro after 8-MOP plus UVA (text-fig. 2) was similar to that found in leukocytes of patients during PUVA treatment (≤60% inhibition in [^{3}H]dThd incorporation) (text-fig. 3). This finding is consistent with the thesis that the decreased DNA synthesis observed in vivo is a direct effect of the 8-MOP plus UVA treatment. Further, the crude assumptions made in predicting leukocyte UVA radiation exposure (*see* above) yield approximately congruent results: Thus 1,000–15,000 J·m^{-2} UVA radiation exposure after 8-MOP sensitization in vitro resulted in 40–60% inhibition of DNA synthesis (text-fig. 2); these values are similar to those observed following skin exposure of 50,000–300,000 J·m^{-2} in vivo (text-fig. 3).

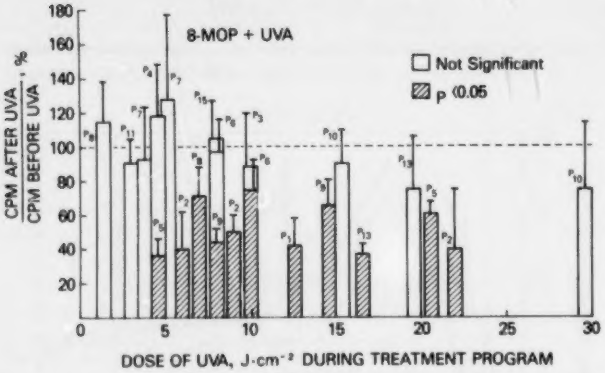


TEXT-FIGURE 1.—Filtering of PUVA fluorescent lamp radiation by plate glass or by human epidermis. The spectral irradiance of a Sylvania FR40T12 PUVA lamp operated at 115 V was measured at a distance of 2 m with and without a 6-mm plate glass filter. Predicted spectral irradiance with unpigmented or pigmented epidermis as a filter is also shown [reproduced from (*18*)].

DNA synthesis was similarly inhibited in the lymphoblastoid cells after UVA radiation exposure and was further decreased by pretreatment with 8-MOP (text-fig. 4). Within the range of doses studied, a tenfold increase in 8-MOP concentration resulted in an increase of approximately 20% in the extent of inhibition of [^{3}H]dThd incorporation, while



TEXT-FIGURE 2.—DNA synthesis in human lymphocytes after 8-MOP plus UVA in vitro. Relative effect of in vitro exposure to UVA radiation and UVA plus 8-MOP (1.0, 0.1, and 0.01 μg 8-MOP/ml) on [^{3}H]dThd (^{3}HTdR) incorporation in lymphocytes from normal donors [modified from (*17*, *18*)].



TEXT-FIGURE 3.—Effect of in vivo PUVA on leukocyte DNA synthesis. Change in [^{3}H]dThd incorporation in leukocytes from patients with psoriasis in relation to UVA radiation exposure during PUVA treatment program [reproduced from (*6*)].

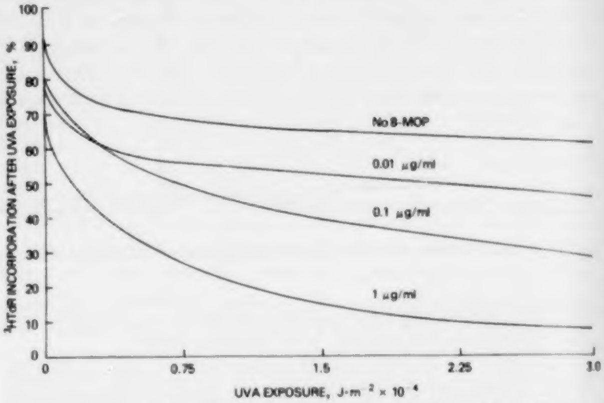
a tenfold increase in UVA radiation exposure resulted in an approximately 30% increase in the extent of inhibition of [^{3}H]dThd incorporation.

EFFECT OF 8-MOP PLUS UVA TREATMENT ON LYMPHOID CELL SURVIVAL

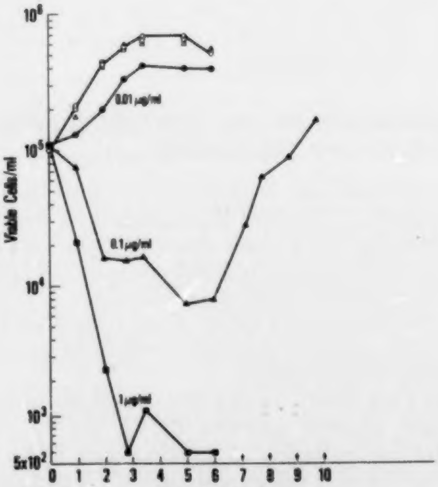
Cell proliferation ability could be evaluated in the lymphoblastoid cells after 8-MOP plus UVA treatment. Proliferation was measured by two methods: by daily hemacytometer counts of trypan blue dye-excluding cells and by growth of small numbers of cells in microtiter wells (*19*). Untreated cells grew exponentially in culture (text-fig. 5). This growth rate was not altered by treatment with either 1 μg 8-MOP/ml alone or 15,000 J·m^{-2} UVA radiation alone. Treatment with 8-MOP followed by UVA resulted in a dose-dependent decrease in cell proliferation. Thus pretreatment with 1 μg 8-MOP/ml followed by 15,000 J·m^{-2} UVA radiation resulted in no detectable viable cells after 1 week in culture.

Dose-dependent decreased cell survival was also evident when the microtiter well cloning method was used (text-fig. 6). UVA radiation exposure of 7,500 J·m^{-2} after pretreatment with 1.0, 0.1, or 0.01 μg 8-MOP/ml resulted in survivals of 0.03, 6, and 80%, respectively. Neither 8-MOP treatment alone nor UVA radiation exposure alone significantly reduced cell survival.

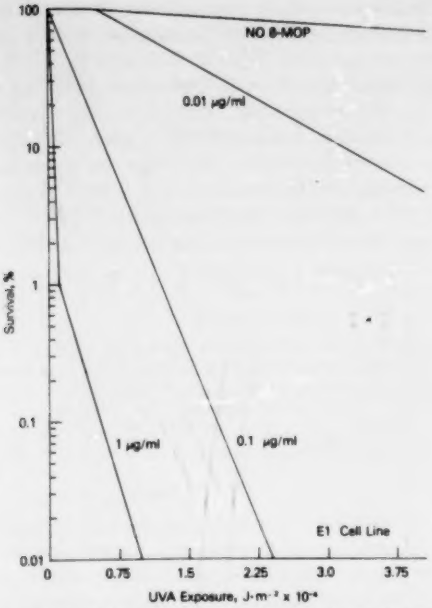
The in vitro assay permits correlation of decreased DNA synthesis immediately after 8-MOP plus UVA treatment with the subsequent cell survival (text-fig. 7). Survival was not altered by treatment which resulted in 60–70% of control [^{3}H]dThd incorporation remaining. However, treatment-induced reduction in [^{3}H]dThd incorporation to 50% of that of the control was associated with approximately 0.5% sur-



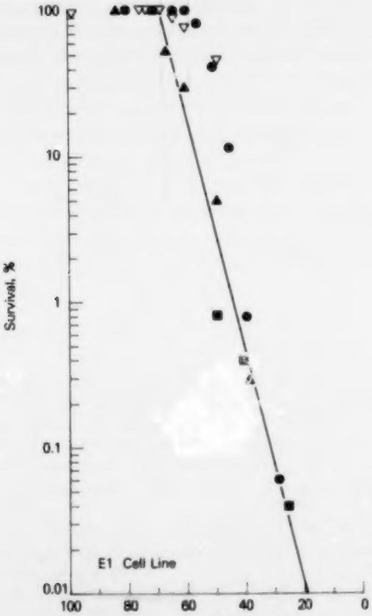
TEXT-FIGURE 4.—DNA synthesis in a human lymphoblastoid cell line after 8-MOP plus UVA treatment in vitro. Relative effect of in vitro exposure to UVA radiation and UVA plus 8-MOP (1.0, 0.1, and 0.01 μg 8-MOP/ml) on [^{3}H]dThd (^{3}HTdR) incorporation in lymphoblastoid cell line E-1 [modified from (*17*, *18*)].



TEXT-FIGURE 5.—Lymphoblastoid cell viability after 8-MOP plus UVA treatment in vitro. E-1 cells were treated with 0, 0.01, 0.1, and 1.0 μg 8-MOP/ml and were then exposed to 15,000 J·m^{-2} UVA radiation. Control cells received no treatment or received 0.1 μg 8-MOP/ml alone. Cell viability was determined by daily hemacytometer counts of cells that excluded trypan blue [reproduced from (*20*)].



TEXT-FIGURE 6.—Survival of human lymphoblastoid cells after 8-MOP plus UVA treatment in vitro. Log-phase cells were treated with 0, 0.01, 0.1, or 1.0 μg 8-MOP/ml and were exposed to UVA radiation. Survival was measured by extrapolation from growth curves and by growth in microtiter wells [modified from (*18*)].



TEXT-FIGURE 7.—Relation of lymphoblastoid cell survival to DNA synthesis inhibition after 8-MOP plus UVA treatment. Mean survival after treatment with 0.01 (●), 0.1 (▲), 1.0 (■), or 0 (▽) μg 8-MOP/ml plus UVA was calculated from text-fig. 8 and was compared to the mean determinations of [^{3}H]dThd (^{3}HTdR) incorporation remaining (text-fig. 4). The coefficient of correlation between the log of the surviving fraction and the percent [^{3}H]dThd incorporation was 0.91 [reproduced from (*18*)].

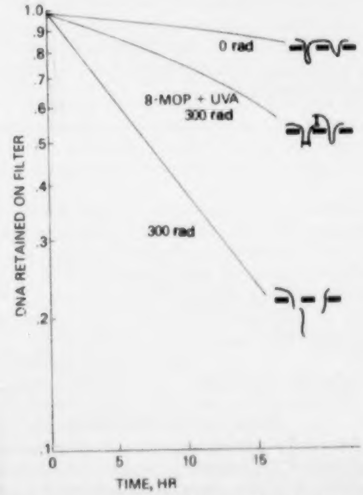
vival. Similar survival was observed at similarly inhibited [^{3}H]dThd incorporation with different combinations of 8-MOP plus UVA. Some psoriasis patients receiving PUVA therapy had 50% reduction in leukocyte DNA synthesis immediately after treatment (text-fig. 3). This in vitro assay predicts that the proliferative ability of these cells would be impaired.

INDUCTION OF DNA CROSS-LINKS BY 8-MOP PLUS UVA

DNA cross-link induction in vitro was measured by a very sensitive technique known as alkaline elution (text-fig. 8) (*18, 20, 48, 49*). Cells in which DNA was labeled with radioactive dThd were irradiated with 300 rad X-ray so that the DNA would be broken into small fragments. The cells were layered on polyvinyl chloride filters with large (2-μm) pores and were then lysed. The DNA was slowly eluted with an alkaline solution at pH 12.1. The fragmented DNA was eluted through the filter relatively rapidly. DNA fragments that are cross-linked are retarded in their passage through the filter and are eluted more slowly.

This difference in elution rates may be used to measure DNA cross-links. Text-figure 9 shows that treatment of cells with 8-MOP plus UVA retards the elution of fragmented DNA. The extent of cross-link formation is related to both the 8-MOP concentration and the UVA exposure (text-fig. 10).

The extent of DNA cross-linking may be correlated with the inhibition of [^{3}H]dThd incorporation (text-fig. 11) measured immediately after PUVA treatment. When DNA synthesis was less than 50% that of the control, a dose-dependent increase in 8-MOP-DNA cross-linking was detected. Similarly, a linear relationship between cell survival and induction of DNA cross-links was detected (text-fig. 12). This

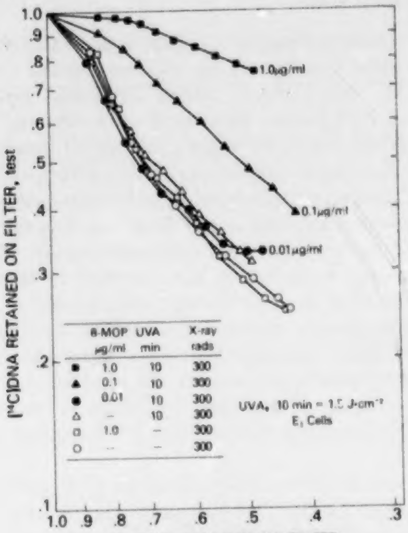


TEXT-FIGURE 8.—Alkaline elution technique for detection of DNA cross-links. DNA from untreated cells was eluted very slowly through the filter (*top curve*). Exposure to 300 rad X-radiation fragments the DNA resulting in more rapid elution (*bottom curve*). DNA cross-linked before 300 rad X-radiation has an intermediate elution rate (*middle curve*). (Diagram courtesy L. Cohen.)

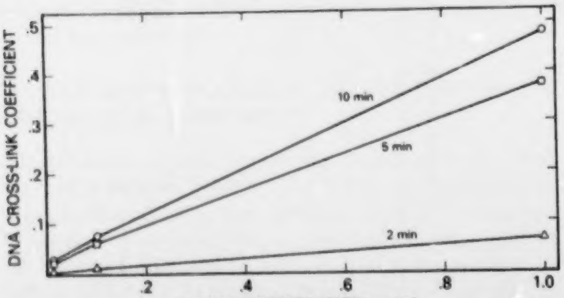
suggests that the cytotoxic effects of photoactivated 8-MOP in human lymphoid cells may depend on DNA interstrand cross-links.

IMMUNOLOGIC EFFECTS OF 8-MOP PLUS UVA TREATMENT IN VITRO

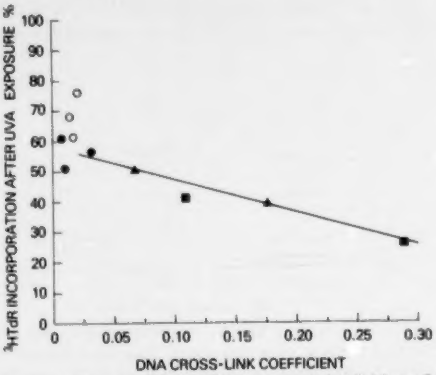
The in vitro assay described was used to measure the effect of 8-MOP plus UVA on immune reactivity (*21*). The mixed leukocyte culture reaction was chosen as an assay of immune histocompatibility. Leukocytes from a normal donor were treated with 8-MOP followed by UVA exposure and were then mixed with leukocytes from an allogeneic donor. In this experiment, known as the two-way mixed leukocyte reaction, leukocytes from each individual stimulate division of T-lymphocytes from the other individual. DNA synthesis was determined after 6 days in culture (text-fig. 13). We see that treatment with 8-MOP plus UVA could completely abrogate the two-way mixed leukocyte



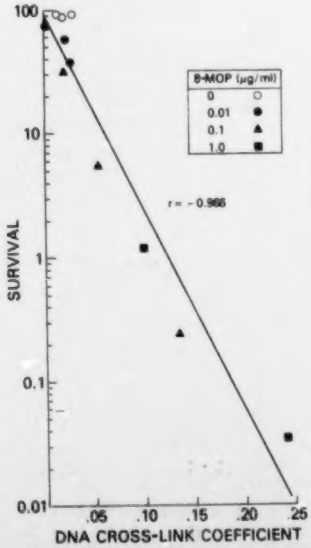
TEXT-FIGURE 9.—Measurement of 8-MOP–DNA cross-links by alkaline elution. [^{14}C]dThd-labeled human lymphoblastoid cells were treated as indicated, exposed to 300 rad X-radiation, and then mixed with [^{3}H]-dThd-labeled untreated mouse L1210 leukemia cells (internal standard) that had received 150 rad X-radiation. The cells were lysed on the membrane filter, and alkaline elution of the DNA was performed for 16 hr. The fraction of the ^{14}C-labeled DNA retained on the filter was plotted as a function of the retention of the ^{3}H-labeled DNA internal standard. Under these conditions, increased DNA retention indicates DNA cross-linking [modified from (*20*)].



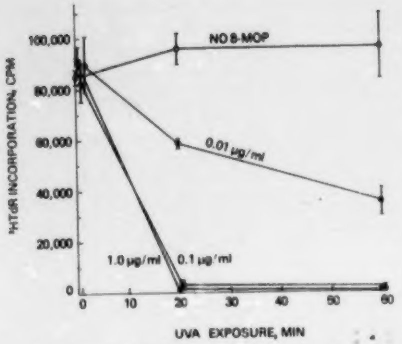
TEXT-FIGURE 10.—DNA cross-link coefficient as a function of 8-MOP concentration and UVA exposure. Human lymphoblastoid cells were treated with 0.01, 0.1, or 1.0 μg 8-MOP/ml and were then exposed to 15,000 J·m^{-2} (10 min), 7,500 J·m^{-2} (5 min), or 3,000 J·m^{-2} (2 min) UVA radiation. DNA cross-linking was measured by alkaline elution as indicated in text-fig. 9, and the DNA cross-link coefficient was calculated for each combination of 8-MOP and UVA. The DNA cross-link coefficient increased linearly with increasing 8-MOP concentration at each UVA radiation exposure level [modified from (*20*)].



TEXT-FIGURE 11.—Relationship of DNA synthesis inhibition after 8-MOP plus UVA treatment to DNA 8-MOP cross-link induction. Human lymphoblastoid cells were incubated with 0 (○), 0.01 (●), 0.1 (▲), or 1.0 (■) μg 8-MOP/ml and were exposed to UVA radiation. [^{3}H]dThd (^{3}HTdR) incorporation was determined from the curves in text-fig. 3 for each combination of 8-MOP and UVA. The DNA cross-link coefficient was determined by use of the data in text-fig. 10 [reproduced from (*20*)].



TEXT-FIGURE 12.—Relationship of DNA cross-link coefficient to cell survival after treatment with 8-MOP plus UVA. Survival data of E-1 cells after treatment with 8-MOP plus UVA were obtained from text-fig. 6 and DNA cross-link coefficient data were obtained from text-fig. 10. r =coefficient of correlation. Note that combinations of 8-MOP plus UVA yielding similar percent survivals also had similar DNA cross-link coefficients [modified from (*20*)].



TEXT-FIGURE 13.—Effect of 8-MOP plus UVA on mixed leukocyte reaction. Leukocytes from a normal donor were treated with 0, 0.01, 0.1, or 1.0 µg 8-MOP/ml followed by UVA radiation and were then mixed with untreated leukocytes from an allogeneic normal donor. DNA synthesis was determined as [^{3}H]dThd (^{3}HTdR) after 6 days' incubation. (Kraemer K, Levis W, Cason J: Unpublished data.) [For further details, *see* (21).]

reaction. Similar experiments with one-way mixed leukocyte reactions demonstrated dose-dependent reductions in both stimulating ability and mixed leukocyte culture reaction-induced proliferation of peripheral blood leukocytes in vitro.

OTHER IN VITRO STUDIES

This assay has also been used to measure the frequency of 8-MOP plus UVA-induced SCE in vitro (*18*). We found at most a twofold increase in SCE.Higher doses of UVA radiation resulted in markedly increased cytotoxicity. These findings are in accord with the observations of Burger and Simons (*50*) on the failure to detect increased SCE in leukocytes of patients receiving PUVA therapy.

Psoriasis patients pretreated with oral retinoids have been reported to respond more rapidly to PUVA therapy (*51*). Accordingly, we decided to examine the effects of retinoids by use of the in vitro assay. Pretreatment of lymphoblastoid cells with 13-*cis*-retinoic acid for 15 minutes before 8-MOP plus UVA exposure did not significantly alter DNA synthesis or cell survival (*18*).

Modification of Photocarcinogenesis by Chemical Agents[1]

Frederick Urbach, *M.D.,*[2] **P. Donald Forbes,** *Ph.D.,*[2] *and* **Ronald E. Davies,** *Ph.D.*[2,3]

ABSTRACT—The evidence is long standing and compelling that chemical agents can modify the carcinogenic effects of light. Various types of chemical–light interaction are discussed, and events in chemical photocarcinogenesis, chemically enhanced photocarcinogenesis, and promotion of photocarcinogenesis are described. Specific examples of each type of process are given, and the importance of interaction of various wavelengths of UV radiation for these processes is stressed.—JNCI 1982; 69:229–235.

This paper is the result of more than a quarter of a century of research on photocarcinogenesis. It is widely accepted that UV radiation is the environmental agent most closely associated with the common forms of skin cancer, i.e., basal and squamous cell carcinomas. There is compelling evidence, based on both geographic and anatomic distribution of tumors, which suggests a causal association modified by genetic and occupational factors (*1*). Furthermore, animal studies have shown that UV radiation is sufficient for the production of squamous cell cancer of the skin (*2, 3*). This type of cancer is the single category of human cancer whose cause is most closely related to UV radiation (*1*).

The evidence is long-standing and compelling that chemical agents can modify the carcinogenic effect of light (*4–12*). As a matter of fact, the first experimental demonstration that one can induce skin cancer in animals with UV radiation was Findlay's in 1928 (*13*). His primary interest was in chemical carcinogenesis. He treated animals with coal tar, irradiated them with mercury arcs, and produced more tumors than if he had used tar alone. Being a good scientist, he ran a control experiment with UV radiation alone; this treatment also induced skin cancer, though not as much was induced as when the combined treatments were used. So this observation that chemical agents can modify the carcinogenic effect of light is clearly not new.

Although UV radiation may be the single most important etiologic agent in human skin cancer (≈400,000 new cases of nonmelanoma skin cancer/yr occur in the United States), nevertheless, the importance or the degree to which chemicals modify the effect of UV radiation on human skin is really not known.

TERMINOLOGY

Before giving a summary of our work, we need to define certain terms that will be used. These definitions may not be the same as everyone else's definitions, but at least our meaning will be clear.

The first concept to be defined is that of "carcinogenesis." As far as we are concerned, carcinogenesis refers to a response by a multicellular biologic system to a physical, chemical, or biologic stimulus; the agent capable of eliciting this response is called a carcinogen. The type of agent is usually specified, e.g., a "chemical" carcinogen or a "physical" carcinogen. The resulting process is similarly qualified, e.g., chemical carcinogenesis or physical carcinogenesis.

The term "photochemical carcinogenesis," as we use it, refers to the production of tumors in response to a combination of light and chemical. This use implies that the response is uniquely associated with a *combination*, and thus both elements must be present simultaneously if we are going to talk about photochemical carcinogenesis. Conceptually, the process is independent of the individual carcinogenicity of either the light or the chemical. In practice, these independent activities cause very serious problems in the identification and interpretation of the results.

Two other terms widely used are "initiation" and "promotion." These are complementary terms that describe certain interactive processes. An *initiator* is a carcinogen which, under the conditions of a particular experiment, may be an inadequate stimulus for the production of overt tumors but which, under varying conditions of dose, application frequency, or route of administration, is expected to produce tumors.

In contrast, a *promoter* is considered to be incapable of eliciting tumors under any conditions. However, after the action of an initiator, a promoter stimulates the appearance and growth of presumptive tumors; this phenomenon is generally explained in terms of two or more stages in the carcinogenic process.

There is obviously ambiguity because of the difficulty of defining a compound as being totally noncarcinogenic and therefore qualified to be a promoter. It is also conceivable that a compound can have such low carcinogenic activity that it can be detected only by its capacity for promotion.

Also important is the concept of "*cocarcinogenesis*," which has changed in the last 2 years. For a long time, cocarcinogenesis was used interchangeably with promotion, but it is not any more. Our use of the term will mean *the specific combined activity of two effective carcinogens*, although one or both may be used at a level too low to produce carcinogenesis by itself. It is possible that there is no fundamental difference between cocarcinogenesis and promotion, and lots of better people than we have argued this point to death.

ABBREVIATIONS USED: ALS=antilymphocyte serum; BP=benzo[*a*]pyrene; DMBA=7,12-dimethylbenz[*a*]anthracene; FS=fluorescent sun; MCA=3-methylcholanthrene; 8-MOP=8-methoxypsoralen; RA=retinoic acid.

[2] The Center for Photobiology, Skin and Cancer Hospital, Temple University School of Medicine, Philadelphia, Pa. 19140.

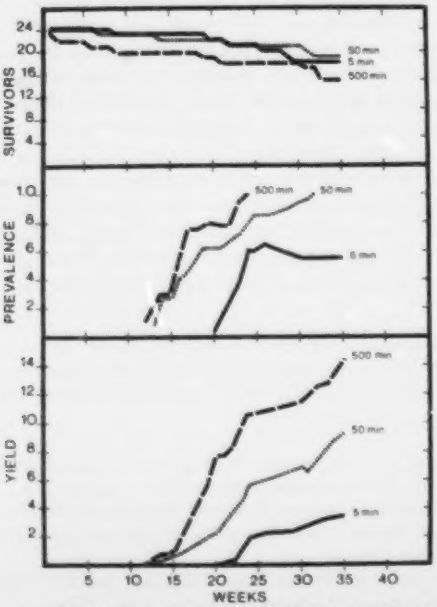
[3] We acknowledge the work on light sources and measurements done by Mr. Daniel Berger and the genetic engineering of animal strains done by Dr. Stanley Mann, both in our laboratory.

Finally, we will use the term "*chemically enhanced photocarcinogenesis.*" You will notice a difference between the terms photochemical carcinogenesis and chemically enhanced photocarcinogenesis. In photochemical carcinogenesis, the chemical and the light must be present at the same time. In chemically enhanced photocarcinogenesis, the photochemical process serves as a promoter, and the carcinogenic light is the initiator.

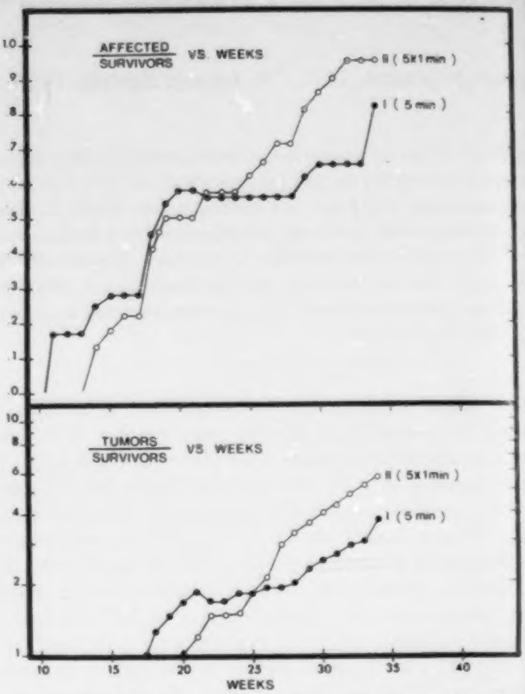
The difference between chemically enhanced photocarcinogenesis and chemical promotion, as, for instance, with croton oil, lies in the fact that the former involves a photochemical process and the latter does not. One can obviously get cocarcinogenesis of this kind as well. The distinction between these various possibilities can impose methodologic problems. Such a distinction may be of very limited significance from a regulatory point of view, but these concepts are important because, under real conditions, one effective carcinogen (some form of radiation) is normally inevitably present. Sunshine, for example, always has some carcinogenic component, although it may be at ineffective levels; thus promotion or cocarcinogenesis may be of great importance.

PHOTOCARCINOGENESIS

In addition to the problems with chemical carcinogens, some very real problems in photocarcinogenesis have to do with only the physical aspect. The data from one particular photocarcinogenesis experiment are shown in text-figure 1. All animals are a strain of hairless mice irradiated with a solar simulator that contained carcinogenic UV radiation; absolutely no chemical was present, and the daily UV radiation dose was given for 5, 50, or 500 minutes/day. The total amount of radiation per day, per month, and per week is the same. The only difference is the rate of administration. Yield refers to the number of tumors per animal, and prevalence, the percentage affected. One can easily see that if the radiation exposure is protracted, many more tumors develop, and tumors develop much sooner.



TEXT-FIGURE 1.—Effect of protracted UV irradiation. SK/h-1 mice were given the same daily doses of UV radiation for 5, 50, or 500 min. *Note* differences in proportion of mice with tumors (prevalence) and average number of tumors per survivor (yield).



TEXT-FIGURE 2.—Effect of daily UV radiation dose when given in one 5-min period or in five 1-min periods 1 hr apart.

The question of course was, does this have to do with just the radiation intensity? We gave the dose for 5 minutes or in five 1-minute doses 1 hour apart so that the same time had elapsed. As seen in text-figure 2, there is very little difference between the two dose regimens as far as tumor development is concerned. We conclude that different dose rates are very important in photocarcinogenesis, and dose rates become another confounding factor to combine with such things as the animals' genetic makeup.

In table 1, classification or postulation of the reasonable possibilities for interactions of light and chemicals has been attempted. Some of these interactions we know exist. Others are just suggested. Two types of radiation, either noncarcinogenic or cancer producing, can occur, as can the same two types of chemicals.

An example of interactions that we know of is noncarcinogenic light and a noncarcinogenic chemical (anthracene), which will result in phototoxicity without photocarcinogenesis (*6*). But it is also possible to use noncarcinogenic light (UVA radiation, 320–380 nm) and 8-MOP (a noncarcinogenic chemical) to get photochemical carcinogenesis (*6*).

In the interaction categories, we have emphasized the distinction between *photochemical carcinogenesis*, for which we really have only one good example (interaction of noncarcinogenic light and the noncarcinogenic chemical 8-MOP)

TABLE 1.—*Interaction among light, chemicals, and biologic targets*[a]

Light	Chemical	
	Noncarcinogenic	Carcinogenic
Noncarcinogenic	*Phototoxicity* *Photochemical carcinogenesis* Photochemistry Optical filtration	*Photochemistry* *Phototoxicity* Promotion Host effects Optical filtration
Carcinogenic	*Optical filtration* *Promotion* *Photochemical cocarcinogenesis* *Host effects* Chemically enhanced photocarcinogenesis Phototoxicity Photochemistry	*Photochemistry* *Cocarcinogenesis* *Optical filtration* Chemically enhanced photocarcinogenesis Phototoxicity

[a] *Underlined categories* include known examples, and the remainder are not demonstrated or are of uncertain significance. Reproduced from (*8*).

and in which initiation of carcinogenesis occurs via photoexcitation, and *chemically enhanced carcinogenesis*, in which the chemical modifies the way in which the biologic targets respond to light. In the other interactions, the chemical can be altered, as with DMBA (*14*).

Until recently, few studies have been designed to distinguish between these various types of interactions. Unambiguous interpretations are generally impossible in studies in which polychromatic light sources and phototoxic or photolabile carcinogens were used intercurrently, unless the studies were specifically designed to look for this. That is a problem with a lot of the older studies. All kinds of interactions likely took place, but unless the study was specifically designed to examine these interactions, interpretation will be difficult. An example of this problem is DMBA, a highly carcinogenic compound, that when irradiated undergoes photo-oxygenation and rearrangements (*14*) with either a loss or a marked reduction of carcinogenicity.

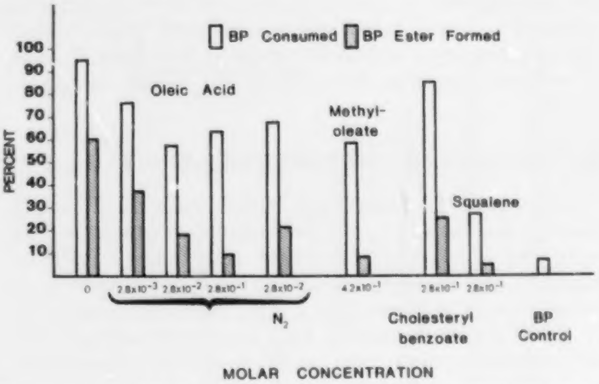
As an aside, this whole series of experiments started because it was noted in some straight carcinogenesis experiments that animals kept on the top of a tier of racks in the animal colony developed much less skin cancer than those animals kept five racks below, i.e., on the bottom. The difference was purely proximity to ordinary, plain room-illuminating fluorescent lamps. A whole series of studies then ensued which showed that under appropriate circumstances a lot of the carcinogen, either MCA or DMBA, on the animal is destroyed before the carcinogen ever has an effect on the skin.

The alkyl-substituted polynuclear aromatic hydrocarbons such as DMBA and MCA are readily degraded by the kind of polychromatic light from the solar simulators that we use in our experiments. In contrast, BP is relatively light-stable. BP is relatively degradable in the presence of free carboxylic acid, however. In the presence of saturated fatty acids, a peculiar kind of photoacyloxylation develops. Text-figure 3 shows some of these results.

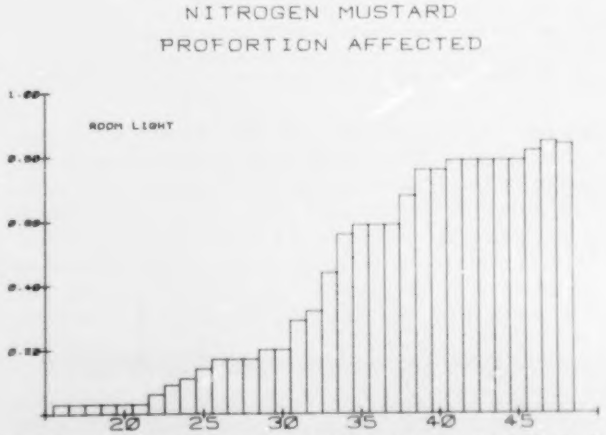
With unsaturated fatty acids the acylation is suppressed, but BP is consumed. Interestingly, these compounds of BP are extremely potent primary irritants although they do not seem to be carcinogenic. And since human skin, unlike animal skin, is covered with a film of fat containing free fatty acids, these reactions of BP with fatty acids may be of considerable significance not only from the point of view of irritancy but also perhaps even more from the point of view that BP is consumed. BP is the main carcinogen that everybody incriminates when they talk about shale oil or tar or whatever because BP is relatively photostable and therefore easily found in nature. Photoacyloxylation may very well be an important reaction, which incidentally takes place in the presence of light.

COCARCINOGENESIS

Cocarcinogenesis is another aspect of the problem. Nitrogen mustard, when painted on the skin of mice, is a carcinogen. We have been interested in nitrogen mustard because, as you know, it is used topically in the treatment of mycosis fungoides, and we have actually seen some keratoses and a few cancers in these treated patients. Text-figure 4 shows the results in hairless mice painted with nitrogen mustard.



TEXT-FIGURE 3.—Effect of unsaturated compounds on photoacyloxylation. Reaction of BP with *n*-caproic acid.



TEXT-FIGURE 4.—Results obtained in hairless mice painted daily for 5 wk with 20 µl of 0.02% nitrogen mustard in methanol (4 mg/mouse/day). *Ordinate values*=affected/survivors; *abscissa values*=wk.

You can see the number of tumors per survivor—you get a pretty good yield at the end of 50 weeks or so. Nitrogen mustard is, indeed, a complete carcinogen.

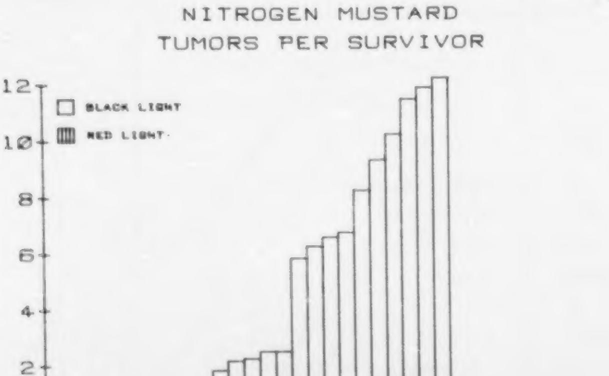
An interesting result is what happens when one irradiates nitrogen mustard-treated mice. Here one has a carcinogen, and in this case one is using a black light fluorescent lamp, unfiltered so it contains some UVB radiation (280–320 nm), but it primarily contains UVA radiation (320–380 nm). Text-figure 5 shows rather strikingly the huge potentiation of light plus nitrogen mustard, whereas, if one uses red light, which is totally inactive, one sees the background tumor incidence of the nitrogen mustard alone.

So in this case, there is cocarcinogenesis with two known carcinogens: The amount of UVB radiation is way below the threshold which is required to produce cancer in this period of time in these animals treated concurrently with nitrogen mustard. And incidentally, the nitrogen mustard is not phototoxic in the standard phototoxicity test. Even though dose-response data are insufficient at this time to permit precise comparison, it appears that the effect of the two carcinogens involved is additive; thus this seems to be a noninteractive form of cocarcinogenesis.

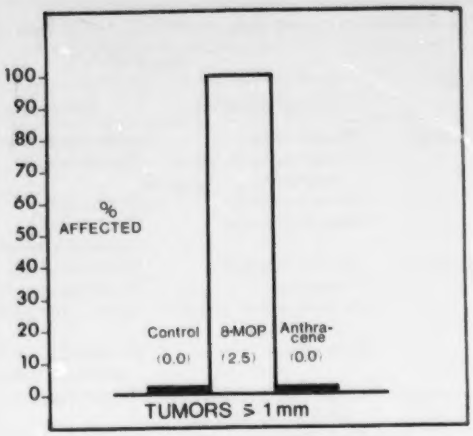
Since both nitrogen mustard and UV radiation are effective skin-pigmenting agents, we repeated these studies with pigmented hairless mice, and we produced lovely, strong hyperpigmentation as well as tumors in these animals. The interesting thing was that none of the tumors were pigmented.

PHOTOCHEMICAL CARCINOGENESIS

Let me go on to what perhaps may be the most important aspect of this paper, i.e., photochemical carcinogenesis. Two groups of workers have provided unambiguous evidence that 8-MOP can mediate photochemical carcinogenesis in the absence of radiation that is itself photocarcinogenic (*6, 9*). Both groups of workers have irradiated animals with very carefully filtered UVA radiation sources; in the control experiment that ran concurrently, no animal developed any tumor when the UVA radiation source was used alone (*6, 9*). The evidence is not clear at this moment for photochemical carcinogenesis with any compound we have tested or found in the literature, except for 8-MOP and some closely related psoralens.



TEXT-FIGURE 5.—Potentiation effect of light plus nitrogen mustard. Mice were treated as specified in legend to text-fig. 4 and were irradiated continuously with either UVA (black-light lamps) or red fluorescent lamps. *Note* minimal effect with red light. *Ordinate values*=No. of tumors per survivor; *abscissa values*=wk.



TEXT-FIGURE 6.—Results at 57 wk of exposure to chemical and UVA radiation. Hairless mice irradiated with UVA (black-light lamps F40T12BL which contain 1.5% UVB radiation) had been treated with 0.01% 8-MOP or 0.1% anthracene. *Note* marked enhancement of photocarcinogenesis with UVA radiation and 8-MOP but lack of effect with UVA radiation and anthracene.

Another compound in which we were interested because it is an extremely good topical phototoxic agent was anthracene. In text-figure 6 are the results of exposure to the chemical and UVA radiation. At the end of 57 weeks, 90% of the animals treated topically with 8-MOP had tumors, with an average number of 2.5 tumors/animal, and although the anthracene was phototoxic, no tumors developed.

This is seen in a different form in text-figure 7. In this case, the light source was a solar simulator, which contains UVB radiation and a lot of UVA radiation in roughly the same proportion as found in sunlight. The radiation exposure itself is carcinogenic. As can be seen for the vehicle control at the end of 36 weeks, 90% of the animals receiving it have tumors, and the animals have an average of about 12 tumors/survivor. With the 8-MOP, however, the onset of tumors is at 16 weeks instead of at 24 or so weeks. At 24 weeks, 100% of the animals have tumors, and the average number of tumors per survivor is 28. At 57 weeks, with topical 8-MOP and UVA radiation *without* UVB radiation, 100% of animals had tumors, with an average tumor number of 2.5. The presence of UVB radiation markedly enhances the photocarcinogenic effect of 8-MOP. Anthracene had no effect.

We looked at a number of photodynamic compounds, compounds that require oxygen to sensitize, that are apparently primarily membrane-effective, although in tissue culture they can affect DNA. In the intact animal, we hypothesize that the effect on the membrane is such that phototoxicity develops, and not much compound gets into the cell to affect DNA. Certainly, anthracene does not enhance photocarcinogenesis; neither does protoporphyrin, as based on the studies of Klaus Wolff (personal communication).

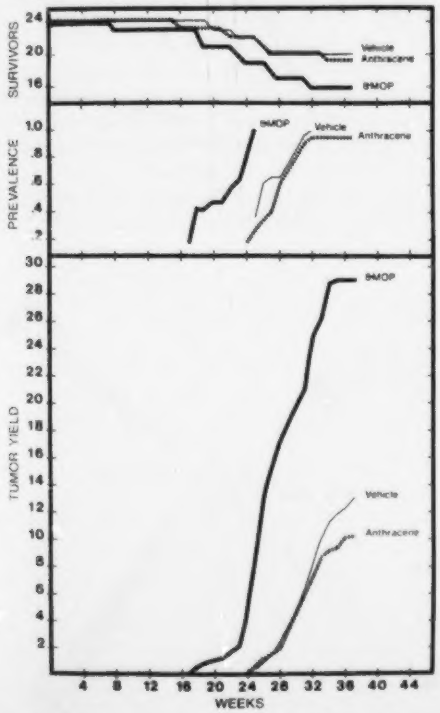
One other compound that we have looked at is amyl *o*-dimethylaminobenzoate. While amyl *p*-dimethylaminobenzoate is a good sunscreen, we find that amyl *o*-dimethylaminobenzoate is a very good phototoxic agent. We have used amyl *o*-dimethylaminobenzoate in this same kind of experiment, and we produced no photochemical carcinogenicity. All these compounds were tested so that the animals treated were kept in a mild state of chronic phototoxicity—not badly damaged, but sort of light pink.

PROMOTION

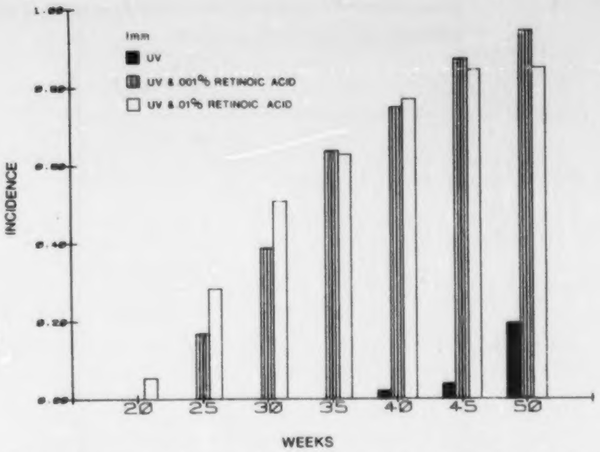
It has been shown that one can give mice small amounts of UV radiation (UVB) in an induction-promotion experiment, and when one paints the mice with croton oil, the mice develop tumors (*2, 7*). *All-trans*-RA acts similarly in an intercurrent experiment. One irradiates animals with a solar simulator, set so that roughly 15% of the animals will at 45 weeks have tumors 1 mm or more in diameter. And if one paints the animals with *all-trans*-RA just after the irradiation (because one certainly does not want to irradiate RA, for it is photolabile) 7 days/week, there is apparently an interaction: Photocarcinogenesis is enhanced (text-fig. 8).

This was an intercurrent experiment. Both treatment and radiation were done each day. Neither is *all-trans*-RA carcinogenic per se in lifetime painted animals nor is it phototoxic in skin. So the question now was, is this a promotion effect?

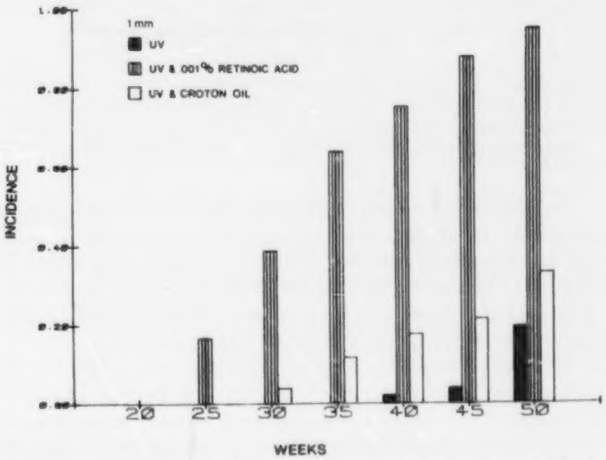
In text-figure 9, we show results from having treated the animals for 6 weeks with UVB radiation. This is not long enough for production of tumors by UVB radiation itself. A week after we stopped irradiating the animals, we painted them for the next 20 weeks with either 0.1% croton oil or 0.001% *all-trans*-RA. This is an initiation-promotion experiment which shows that 0.1% croton oil is a weak promoter and that the RA in this case was as good if not better as a promoter, when the same criterion was used, as was 0.1% croton oil.



TEXT-FIGURE 7.—Effect of pretreatment with 8-MOP, anthracene, or the vehicle methyl alcohol on survival, the proportion of mice with tumors at any time (prevalence), and the average number of tumors per survivor (tumor yield) in groups of albino SK/h-1 mice irradiated chronically with a xenon arc simulator [from (*6*)].

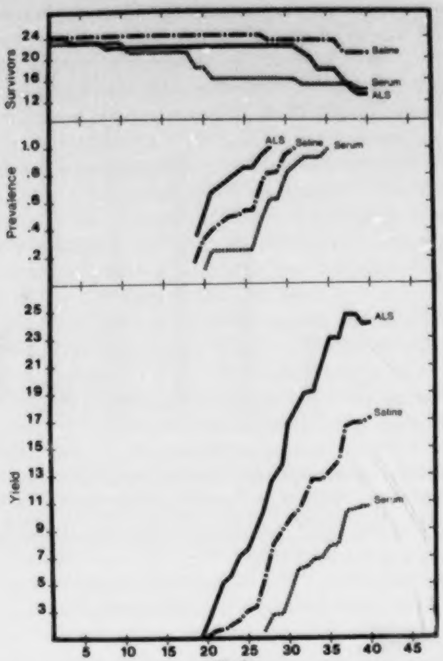


TEXT-FIGURE 8.—Incidence of skin tumors 1 mm in diameter in hairless mice irradiated 7 days/wk with a solar simulator, with a subsequent topical application of 20 µl of either 0.001% or 0.01% *all-trans*-RA acid in methanol. *Note* marked enhancement of photocarcinogenesis by post-treatment with RA [after (*10*)].



TEXT-FIGURE 9.—Results of an initiation-promotion experiment. Mice were irradiated as specified in legend to text-fig. 9 after they had been painted with either 0.001% *all-trans*-RA or 0.1% croton oil in methanol. *Note* promoting effect of croton oil as well as that of *all-trans*-RA.

Having done several experiments that seemed to show that *all-trans*-RA was a promoter of UV carcinogenesis, we did an experiment in which we used benz[*a*]anthracene as an initiator before we used RA, and nothing happened. However, when DMBA was used for initiation, *all-trans*-RA significantly promoted chemical carcinogenesis.



TEXT-FIGURE 10.—Effect of suppression of lymphocytic activity on photocarcinogenesis. Hairless mice were irradiated with a solar simulator after inoculation with rabbit anti-mouse ALS, saline, or normal rabbit serum. *Note* enhancement of photocarcinogenesis by immunosuppression with ALS.

As you might expect, this result was totally unexpected. Retinoids have been used as anticarcinogens; when given orally, vitamin A has been shown to reduce the number of chemically induced papillomas (*4*). So this result was totally unexpected. We do not know why it occurred. All we can say is that *all-trans*-RA is effective as a promoter.

We have inoculated animals (hairless mice) with rabbit anti-mouse ALS for a week before and during standard irradiation. We had 2 control groups: In one, animals were inoculated with saline; in the other, animals were inoculated with normal rabbit serum. Text-figure 10 shows that photocarcinogenesis was significantly increased when lymphocytic activity (presumably T-cell activity) was suppressed.

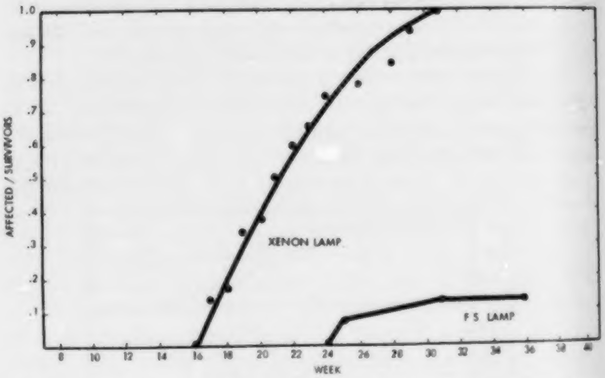
SUMMARY

For interpretation of results when dealing with the interaction of chemicals and light in carcinogenesis, we must consider three aspects simultaneously—light source, chemical, and host. We must first consider the *light source*, and that of course has to do not only with obvious things such as spectrum, with which all of you are familiar, but as I showed you at the very beginning, also with such things as dose rate and frequency and fractionation.

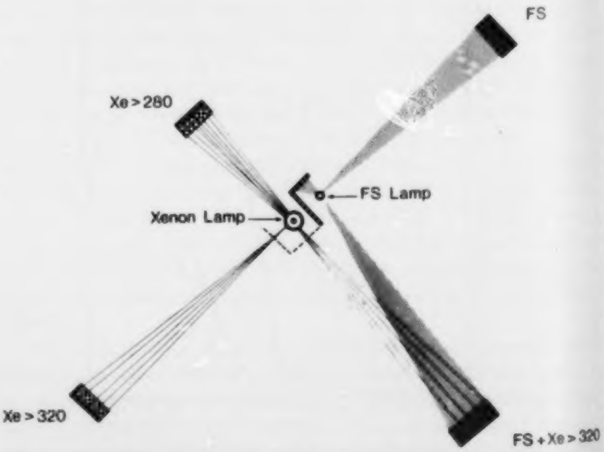
As an example of potential pitfalls, the following work is summarized. We initiated a very simple experiment in which we irradiated 1 group of animals with an FS lamp, which emits nearly pure UVB radiation, and we irradiated another group of animals with a solar simulator, which contains, by our measurements, the same amount (although not the same spectrum) of UVB radiation and also includes a lot of UVA radiation. When the solar simulator was used, the result was a huge increase of skin cancer over that produced by the fluorescent lamps. And that, of course, conclusively proved to us that UVA radiation indeed enhanced photocarcinogenesis, as Willis et al. (*15*) reported for skin erythema (text-fig. 11).

After we discovered the protraction effect described earlier, on review we realized that with the FS lamp the duration of exposure was 2 minutes, and with the solar simulator, the duration was 2 hours. So we began to wonder about our experiment. Repeating the previously described experiment with an FS lamp and solar simulator placed side by side and with the mice located so that the UVB radiation dose rate was similar from both light sources (text-fig. 12), we found that UVA radiation had no effect on UVB radiation photocarcinogenesis. What we had encountered was the "protraction effect."

The next problem, of course, is the interaction of light



TEXT-FIGURE 11.—Tumor prevalence vs. wk of exposure. Xenon lamp contains primarily UVB and UVC (200–280 nm) radiation [from (*1*)].



TEXT-FIGURE 12.—Schematic diagram of lamps and filter arrangement for comparing the effect of UVB radiation with that of UVB plus UVA radiation on photocarcinogenesis [from (*3*)]. Wavelengths are specified in nm.

and chemicals, and one of the things that is of great importance is the fact that UV radiation and visible radiation contain potent photons that are perfectly capable of doing photochemistry, and usually do so. Therefore, you can get photoproducts that may be more carcinogenic, less carcinogenic, more toxic, and certainly different. And depending on when you do what, you can affect the outcome of the experiment.

The next obvious problems are effects such as interactions with cocarcinogens and promoters like nitrogen mustard and RA. There may be any number of such compounds around, so the problem is complicated.

Finally, there is the problem of host modification. In addition to immunologic modification, a study is being done with 10 hairless mouse strains that are genetically different. Just doing straight photocarcinogenesis with the same light source and with the same filters—everything being the same—there is a huge difference in the susceptibility of different mouse strains to photocarcinogenesis, which is just genetically determined.

Different strains of animals have different genetic constitutions, and these differences do not seem to be related to the animals' immune systems. So you better be careful whose mice you use—not because one strain or stock is better than the other, but because each reacts differently and you will get different answers with psoralens, as Fry et al. (*9*) showed.

We are to the point of knowing some of the pitfalls and wanting to do experiments that are meaningful. These experiments will have to be done with very carefully calibrated light sources, with appropriate animals, and in an appropriate fashion. We can now begin to sort out and deliberately develop experiments for definition of specific problems. For instance, we really need to define this business as to whether UVA radiation plus UVB radiation and 8-MOP is really more carcinogenically effective than UVA radiation alone, and over what limits. The preliminary experiments strongly suggest a difference.

Current Status of Predictive Animal Models for Drug Photoallergy and Their Correlation With Drug Photoallergy in Humans[1, 2]

Leonard C. Harber, *M.D.*,[3] **Robert B. Armstrong**, *M.D.*,[3] *and* **Hideyuki Ichikawa**[4]

ABSTRACT—The number of adverse responses considered to be drug photosensitivity reactions account for only an exceedingly small percentage of the total undesirable effects from environmental chemicals. However, the rising incidence of and severe disability resulting from drug photosensitivity, especially when the photosensitivity is of the persistent light reactor type, indicate that increased photobiologic research and development efforts are required. Predictive tests are an obvious approach to minimize or eliminate those chemicals showing a risk-benefit ratio that is undesirable to society in general or to an unknowing individual in particular. Animal models with predictive value for determining the risk of photoallergic contact dermatitis in humans have undergone considerable modification during the past decade. This study reports an improved experimental guinea pig model for inducing photoallergic contact dermatitis to musk ambrette. In contrast to previously described models that used Freund's adjuvant, this model does not require nuchal stripping with cellophane tape. Control studies for primary irritancy, phototoxicity, allergic contact dermatitis, and "angry back" syndrome were included in the experimental design. Only photoallergic contact dermatitis was observed. Although the technique used to demonstrate this phenomenon is conducive to standardization, additional studies are required to ascertain whether or not other chemicals known to be photoallergic in humans can also be demonstrated with this animal model.—JNCI 1982; 69:237–244

The public in general and the scientific community in particular recognize that the introduction of innumerable new chemicals into our environment has been associated with both benefits and risks. Although these agents have been designed to aid the public, some have clearly entailed hazards of varying degree, as exemplified by hepatotoxic effects of vinyl chloride (*1*) and the oncogenic effects of diethylstilbestrol on vaginal tissue (*2*).

A subset of adverse reactions to environmental chemicals is photosensitivity reactions involving the skin. The term "drug photosensitivity" has been used to describe adverse reactions associated with patients exposed to sunlight after they have received particular medications. Although originally used in this limited clinically therapeutic sense, the term has been expanded in recent years to include reactions to chemicals used in cosmetics (*3*), food preservatives (*4*), household cleaners (*5*), fragrances (*6*), agricultural materials (*7*), and industrial by-products (*8*).

While the incidence of drug photosensitivity reactions has been quite low, it appears to be increasing. There is evidence in the literature of tens of thousands of persons affected with drug photosensitivity reactions during recent decades. In addition, there is a particular type of photosensitivity known as a persistent light reaction (*9*) that can be totally disabling. The increasing incidence and severity of this type of photosensitivity problem have served to illustrate the need for further photobiologic research efforts. It would be particularly desirable to have an animal model that could predict the potential of chemicals or drugs for producing the full range of adverse photosensitivity reactions.

Several models have been described and modifications continue to be developed. This paper is restricted solely to the subjects of development and evaluation of animal models for the induction of photoallergic contact dermatitis and for the assessment of their correlation with clinical events and photosensitivity tests in humans.

GENERAL REVIEW

A number of chemicals have been reported to cause photocontact dermatitis. These reactions are mediated by two broad mechanisms of action, phototoxic and photoallergic pathways. Their salient features are noted in table 1 and text-figure 1.

The mechanism involved in photoallergic contact dermatitis is immunologic and of the delayed hypersensitivity type. The role of light is restricted to photochemically altering the hapten or facilitating its combination with carrier protein (*10*). Following formation of this complete "photoantigen," it is believed that this unit is further processed by macrophages and comes in contact with T-lymphocytes in a manner similar to that of antigens associated with an ordinary delayed hypersensitivity immunologic response (*11*). The complete photoantigen is recognized as foreign on subsequent environmental exposure when sensitized T-lymphocytes are now present. An immunologic response is then initiated which results in erythema in laboratory animals and a papulovesicular, eczematous response in humans (*12*). This hypothesis has been supported by both in vitro and in vivo studies. The following are representative examples:

as the macrophage inhibition and lymphocyte stimulation tests, have demonstrated positive results (*13*, *14*).

In Vivo Studies

Passive transfer of photosensitivity to TCSA with the use of peritoneal mononuclear cells from photosensitized guinea pigs has been demonstrated (*15*, *16*). The most comprehensive data in laboratory animals concerning induction of photoallergy to halogenated salicylanilides and its derivatives were those of Morikawa et al. (*17*). Recent studies by M. Takagawa and Y. Myochi (University of Kyoto, Kyoto, Japan) indicate the feasibility of using inbred strains of mice (BALB/c, DBA/2, C3H, and C57BL) for the induction of photoallergic contact dermatitis to TCSA, tribromsalan, and bithionol.

The first induction of experimental photoallergic contact dermatitis in guinea pigs was reported by Schwarz and Schwarz-Speck (*18*) in 1957. Their demonstration used sulfanilamide as a test model. Following this, Vinson and Borselli (*19*) induced contact photoallergic reactions with TCSA. Their technique has been considerably modified but basically confirmed by several other groups (*20–22*). More recently, contact photoallergies to musk ambrette (*22*, *23*) and 6-methylcoumarin (*24*, *25*) have been induced.

The guinea pig is presently the only experimental animal used to demonstrate photosensitivity of the delayed hypersensitivity type in all of the reported photoimmunologic animal studies. Hartley strain albino guinea pigs (375–425 g) are routinely used. Females appear to be preferable because there is likely to be less scratching of phototest sites.

Table 2 lists the techniques of inducing contact photoallergy in guinea pig models. In all the reported models, after induction and a suitable incubation period, elicitation is accomplished by topical application. These techniques are remarkably similar to those reported for inducing reactions in humans (*26*).

Clinical reports of photosensitivity in humans include reports on chlorpromazine (*27*), bithionol (*28*), Jadit (*29*), and promethazine (*30*). Table 3 presents a comprehensive list of agents reported to induce photoallergic contact dermatitis in humans.

Because of the risk and hazards of injury of test subjects by photosensitization (*31*), the following data in laboratory animals are stressed, indicating our preference for the use of a predictive animal-screening test model for photoallergic contact dermatitis before tests are initiated in humans.

Induction Techniques in Guinea Pigs

The typical induction procedure consists of the topical application of a relatively high concentration (10–100 times more than the lowest eliciting concentration) of the photosensitizer followed by UV irradiation. The entire induction procedure involves solely the nuchal region and is repeated five times during a 7- to 10-day period (table 2). Elicitation of photoallergic contact dermatitis is restricted to the depilated surface of the back.

Induction with UVB irradiation.—This model, introduced by Vinson and Borselli (*19*), has undergone numerous modifications and is an excellent one for inducing photosensitivity to halogenated salicylanilides. It uses both UVA and UVB radiations during the induction phase. As mentioned, although it has undergone extensive modification, this widely established model has been duplicated in several laboratories (*20–22*). However, it is ineffective in inducing photoallergy to 6-methylcoumarin and musk ambrette. A possible hazard involves corneal burns from UVB radiation expo-

TABLE 2.—*Techniques used to increase index of photoallergic contact dermatitis in guinea pigs*

Nuchal technique[a]	Example of photosensitizer
UVB radiation	Halogenated salicylanilides
Sodium lauryl sulfate	Halogenated salicylanilides
Skin "stripping" with cellophane tape	Musk ambrette
Stripping plus intradermal injection of Freund's adjuvant	Musk ambrette 6-Methylcoumarin
Intradermal injection of Freund's adjuvant without stripping	Musk ambrette

[a] These procedures precede irradiation of topically applied chemical with UVA radiation.

sure; therefore, the investigator's eyes must be protected with goggles.

Induction with sodium lauryl sulfate.—This model, introduced by Horio (*32*), offers promise and should be further evaluated. The induction procedure consists of the topical application of a 20% aqueous solution of sodium lauryl sulfate to the nuchal area. One hour later the photosensitizer is applied to the same site and immediately thereafter the site is exposed to UVA radiation. The procedure is repeated five to ten times during a 10-day period. The technique appears simple and effective. It is reported to produce a high index of photosensitization to halogenated salicylanilides and bithionol. Unfortunately, there are only limited reports of usage by photobiologists.

Induction with skin stripping with cellophane tape.—The induction phase consists of the repeated application of cellophane Scotch tape to the nuchal site until glistening is noted. The photosensitizer is then applied to this area, after which the site receives UVA radiation. The procedure is repeated three to five times during a 7-day period on the nuchal area. The rationale of stripping is presumed to involve increased percutaneous absorption of the photosensitizer, but the effectiveness of the model may also be related to the inflammatory response. This induction procedure appears analogous to the maximization test in humans and was successful for induction of musk ambrette photosensitivity in guinea pigs (*22*). However, in our studies, it was ineffective in inducing photoallergy to 6-methylcoumarin. A disadvantage of the technique is that a thick crust often forms on the nuchal induction site and impedes absorption.

Induction with Freund's complete adjuvant and cellophane stripping.—Freund's complete adjuvant, injected intradermally, has been demonstrated to increase the incidence of photosensitization to musk ambrette and 6-methylcoumarin in the guinea pig (*23*). This technique involves injecting Freund's adjuvant into four sites at the periphery of the depilated nuchal area, stripping with cellophane tape, applying the test substance, and exposing the region to UVA radiation. During the entire photosensitizing procedure, the adjuvant is injected only once, but the remainder of the induction steps are performed a total of five times (fig. 1). After 2 weeks, photosensitivity is assessed after depilation of the back for the first time, application of the test material to the back, and exposure of the back to UVA radiation (fig. 2). These experiments pose the disadvantage of variations in the manner by which and the extent to which cellophane tape stripping are accomplished and they make it difficult for other investigators to reproduce accurately and uniformly, in a controlled manner, the stripping procedures. Accordingly, the following studies were designed to test whether or not stripping was necessary for induction of photoallergic contact photosensitivity to musk ambrette.

MATERIALS AND METHODS

Experimental animals.—Twenty-three Hartley strain female albino guinea pigs weighing 375–450 g were tested. Musk ambrette (2-methoxy-3,5-dinitro-4-methylbutylbenzene) was used as a test agent. The purity of musk ambrette was assayed by high-pressure liquid chromatography and thin-layer chromatography.

Light sources.—Black light fluorescent tubes (General Electric Co.) emitting radiation in the 320- to 400-nm range were employed. The fluence rate measured at 12.5 cm through 3 mm of window glass was 2.85 mW·cm^{-2}. All black light irradiation (10.2 J·cm^{-2}) is nonerythrogenic in the absence of the photosensitizer.

Induction of photosensitivity in nonstripped nuchal skin.—The nuchal area (2.5×2.5 cm) of 11 guinea pigs was shaved and depilated with Nair, and 0.1 ml of a 10% solution of musk ambrette in acetone was applied. Before this procedure, 0.1 ml Freund's adjuvant (fig. 1) had been injected into four nuchal sites. Five treatments were given during a period of 10–11 days. Each treatment was followed by irradiation with black light fluorescent tubes as previously described.

Induction of photosensitivity in stripped nuchal skin (control).—The nuchal area of 12 guinea pigs was shaved, depilated with Nair, and stripped with cellophane tape for three or four of the five treatments. Freund's adjuvant was injected into four sectors. Musk ambrette (0.1 ml of a 10% solution in acetone) was applied within 15 minutes after stripping. The animals were irradiated with the same doses of light as were used for the nonstripped animals. The sensitization treatment of both the cellophane tape-stripped and nonstripped groups was performed five times during a period of 10–11 days.

Tests for elicitation of contact photosensitivity to musk ambrette.—The guinea pigs were challenged 17–22 days after the last nuchal sensitization exposure. The shaven and depilated lumbar area which had received no previous exposure to musk ambrette or light was demarcated into six sites (2.5×3.5 cm) with masking tape. The animals previously exposed to 10% musk ambrette in their nuchal region were challenged with 10, 1, and 0.1% concentrations of musk ambrette in ethanol on their dorsal lumbar skin (fig. 2). Each concentration (0.1 ml) was applied to symmetrical sites on the left and right sides of the animal. The right side was shielded with light-opaque material. A nonerythrogenic dose (10.2 J·cm^{-2}) from black light fluorescent tubes was administered 30 minutes after application of the challenge solutions.

TABLE 4.—*Induction of photoallergic contact dermatitis to musk ambrette with the use of Freund's complete adjuvant, with and without cellophane tape stripping*

Procedure	Concentration of musk ambrette, %	No. of irradiated animals reacting/total No. of animals irradiated[a]			No. of unirradiated animals reacting/total No. of unirradiated animals
		1+	2+	Total No. of irradiated animals reacting/total No. of animals irradiated	
Nonstripping	0.1	4/11	0/11	4/11	0/11
	1.0	5/11	1/11	6/11	0/11
	10	5/11	1/11	6/11	0/11
Stripping	0.1	4/12	2/12	6/12	0/12
	1.0	6/12	4/12	10/12	0/12
	10	6/12	4/12	10/12	0/12

[a] Grading of reaction: 1+=mild erythema without edema; 2+=moderate to strong erythema without edema.

TABLE 5.—*Control studies for photoallergic contact dermatitis to musk ambrette*

Mechanisms evaluated	Chemical[a]	No. of animals	Result
Phototoxicity	100% musk ambrette	20	No primary irritant or phototoxic reaction noted on first exposure
Allergic vs. photoallergic contact dermatitis related to humans	$NiSO_4$	12	Contact allergy but no photocontact allergy induced with Freund's adjuvant
Allergic reactivity unrelated to humans	$CuSO_4$	12	No induction of allergic or photoallergic contact dermatitis
Nonspecific reactivity, angry back syndrome	TCSA, $CuSO_4$, and musk ambrette	12	No reaction to $CuSO_4$ and musk ambrette in animals photosensitized to TCSA and challenged with TCSA, $CuSO_4$, and musk ambrette

Evaluation of test results.—Erythema on the test sites was evaluated at 24 hours after irradiation with the use of a scoring system ranging from 0 to 3. A score of 1 or higher was considered a positive response.

RESULTS AND CONTROLS

Contact photoallergy to musk ambrette.—As noted in table 4, photosensitization to musk ambrette was induced with both the stripping and nonstripping procedures (fig. 3). The incidence of photosensitization and magnitude of response were greater in the stripped group.

Controls of photoallergy (*table 5*).—So that false-positive photosensitivity responses of a nonspecific nature could be ruled out, attempts were made to photosensitize guinea pigs to nickel sulfate, a known ordinary contact allergen in humans which has induced no cases of photoallergy in humans to date, and to cupric sulfate, a nonallergic agent in humans. Allergic contact but not photoallergic contact dermatitis was induced to nickel sulfate by use of Freund's adjuvant technique (Ichikawa H: Personal communication). Neither allergic nor photoallergic dermatitis was induced with cupric sulfate.

Controls for nonspecific reactivity ("*angry back*" *syndrome*).—Animals photosensitized to TCSA were challenged with TCSA and cupric sulfate. Reactions were noted only at TCSA-treated sites.

Control studies of phototoxicity: Phototoxicity to musk ambrette, anthracene, and 8-methoxypsoralen.—As previously described, 20 guinea pigs with no previous nuchal sensitization to musk ambrette were challenged with 50, 20, 10, 5, 3, and 1% concentrations of musk ambrette in acetone (*32*). With the use of radiation identical to that which elicited photoallergy, none of this group showed any visible reaction.

CONCLUSION

This modified experimental model for inducing photoallergic contact dermatitis in guinea pigs demonstrates the successful induction of photoallergic contact dermatitis to musk ambrette. In contrast to previously described models using Freund's adjuvant, this model did not require stripping with cellophane Scotch tape. Additional studies are needed to further demonstrate the correlation of the results seen with this model with events found in humans.

DISCUSSION

J. Middleton: I have a question with regard to the control animals used in your studies. I have had considerable experience with the Magnusson guinea pig maximization test, which we use in Europe. In this test, if you inject with adjuvant, you can show that you increase the susceptibility not only to sensitization, but also to irritation.

My question is, in the studies you showed us, did you use adjuvant-pretreated animals as your controls? If not, do you think there is a possibility that some of the reactions may be photoirritation rather than photoallergy?

L. C. Harber: Our findings in patch test studies with humans regarding the "angry back" syndrome or "nonspecific" positive patch tests are in accord with those described by Dr. Mitchell. In terms of guinea pigs, however, we have not observed this phenomenon. Unfortunately, I have no direct experience with the Magnusson test, but our photobiology group has assessed in guinea pigs the angry back syndrome in regard to two photosensitizing fragrance materials, musk ambrette and 6-methylcoumarin. Specifically, relevant control studies concerning induction of photosensitization with the use of the Freund's adjuvant technique presented here involved an innocuous agent, cupric sulfate ($CuSO_4$). This compound has no known primary irritant or allergic properties in humans and thus was chosen for our control studies. Two weeks after attempted induction with $CuSO_4$, the animals were challenged simultaneously with 10% $CuSO_4$, 10% musk ambrette, and 10% 6-methylcoumarin. Each animal was assessed in the presence and absence of UVA light; 6 test sites were evaluated in each of 6 guinea pigs. No reactions were seen at any of the 36 sites.

Toxic Effect of Ultraviolet Light on Melanocytes: Use of Animal Models in Pigment Research[1,2]

George Szabo,[3] Frederick B. Blog,[4] *and* **Andrija Kornhauser[5]**

ABSTRACT—Quantitative histologic investigations on the effect of UV radiation on mammalian melanocytes have shown similarities in the response to carcinogenic chemicals, UV radiation, and 8-methoxypsoralen combined with UV radiation. With all three regimens the melanocyte number increased in mice, whereas long-wavelength UV radiation alone did not change the numerical distribution of these cells. Although it is too early to say that similarity in response of these agents indicates identity in harmful effects of these agents, great care should be exercised in the application of psoralens to human skin in a combined treatment with UV radiation.—JNCI 1982; 69:245–250.

A large body of evidence suggests a correlation between exposure to sunlight and the incidence of neoplasms of the skin (*1*). While the biological role of melanin is considered that of protection against harmful effects of UV radiation, the melanocytes (cells responsible for melanin production) are also known to undergo neoplastic changes possibly under the influence of sunlight.

In this article models used in the study of melanogenesis will be discussed followed by a presentation of our data regarding cytologic effects of exposure of mammalian melanocytes to UV radiation (UVA and UVB)[6] with or without treatment of the skin with a known chemical carcinogen (DMBA) or a photosensitizer widely used in treatment of psoriasis (8-MOP).

BIOLOGICAL MODELS IN PIGMENT RESEARCH

We believe that the melanocyte system of the mammalian epidermis is an excellent model for the study of melanogenesis and phototoxicity (*2–4*). This cell type produces a well-definable enzyme (tyrosinase) and a cell organelle (the melanosome). Inside this melanosome, tyrosinase becomes active and melanization takes place utilizing the substrate tyrosine. Finally, the melanosomes are transferred into keratinocytes by a unique cell-to-cell interaction (cytocrine activity). Ultrastructurally, the melanocytes are typical exocrine cells containing rough endoplasmic reticulum, Golgi zone, and melanosomes in various stages of formation (*4*).

These melanocytes are located in the basal layer of the epidermis, and in a dopa-treated epidermal preparation they can be counted easily. In the human epidermis there are about 1,000 melanocytes/mm^2 of skin surface in areas below the neck and about 2,000 in the head region (*5–9*). Although this distribution seemingly follows the extent of exposure to sun, there are some exceptions to this rule, inasmuch as 1,600 melanocytes can be found in some portions of the oral and nasal mucosae, about the same number can be seen in the epidermis of the sole and palm, and about 2,000 melanocytes can be found in the epidermis of the skin of the genital regions (*6*). There is no difference in the melanocyte number when one compares region by region the skin of the different color variants of the same species (*8–11*).

EFFECT OF UV RADIATION ON MAMMALIAN MELANOCYTES

It is well known that, as a first effect of exposure to sun, immediate pigment darkening of the skin can be observed within a few minutes, followed by new melanin formation 2–3 days after the initial exposure (*1*). Several separate steps are involved in this new melanin formation such as the synthesis of the enzyme tyrosinase, the formation of the melanin granule (the melanosome), the activation of tyrosinase within this melanosome, the polymerization of tyrosine into melanin, and the transfer of the melanized melanosome into the keratinocytes of the epidermis.

Solar radiation enhances the tyrosinase activity of melanocytes. This effect is well demonstrated in histologic preparations in which the melanocyte numbers of tyrosine-treated and dopa-treated portions of the same biopsy specimen are compared [*see* table 1 and (*6*)]. In the areas exposed to sun the number of melanocytes reacting with tyrosine is high and close to the number demonstrated with dopa, whereas in nonexposed areas either the tyrosinase reaction is entirely negative or only a very few melanocytes are positive. One should be aware of the fact, however, that tyrosine is also a suitable substrate to demonstrate melano-

[6] The UV spectrum can be divided into three regions: UVA (320–400 nm), noninflammatory and somewhat melanogenic; UVB (280–320 nm), inflammatory and melanogenic; and the germicidal UVC (shorter than 280 nm). UVC is absorbed in the stratospheric ozone layer and thus does not reach the earth's surface.

cytes in the skin areas of sex organs unexposed to solar radiation, which indicates that sex hormones can stimulate melanogenesis in specially receptive areas of the skin (table 1).

The tyrosinase activity of melanocytes is elevated after UV radiation; in addition, after multiple exposures the mitotic activity of melanocytes increases (*12*), resulting in an increase in melanocyte number which gradually returns to the preexposure level after the cessation of exposure (*10, 13*). Consequently, when one compares the numbers of dopa-positive melanocytes between habitually exposed and unexposed areas of the same individuals, one finds that the number is about twice as much on the exposed area than on the neighboring shielded regions (*14*).

It is not a prerequisite, however, that the melanocyte number increases following UV radiation, because if the skin is exposed to a single dose of UV radiation, pigmentation may increase without an increase in melanocyte number (*15*). In the following we shall turn our attention to experimental work on mice whose tail skins were exposed to UVA and UVB radiation (*16, 17*).

The tail skin of the mouse is very similar to human skin: Mouse skin is relatively hairless and contains functioning melanocytes in the basal layer; the epidermis is not as thin as in the general body skin of this species. The dorsal tail skin consists of a bricklike arrangement of pigmented blocks of skin surrounded and separated by nonpigmented areas (*11*). There are about 600 dopa-positive melanocytes per mm^2 in the pigmented areas, and none in between.

To answer the question whether UV light elicits toxicity similar to that of carcinogens or photosensitizers, we extended this study of the effect of UV radiation on skin by treating the skin with a known carcinogen, DMBA, and in separate experiments by treating the skin with the widely used photosensitizer 8-MOP combined with UVA radiation (PUVA).

We found that, in a sense, the mouse tail acts as a photometer (tables 2, 3); i.e., it "distinguished" between UVB and UVA radiation. The melanocyte number did not change after prolonged UVA radiation, whereas it doubled after UVB radiation. When psoralen and UVA radiation treatments were combined (PUVA), the numerical density of melanocytes became almost three times as high as that in normal or UVA radiation-treated animals. DMBA alone or DMBA combined with UVB radiation also resulted in an increase in melanocyte number. The morphologic changes were also revealing: After PUVA, DMBA plus UVB radiation, and UVB radiation treatment alone, melanocytes became large and irregular in shape, and the dendrites of melanocytes were shortened and clumped together. The outer root sheaths of hair follicles became laden with melanocytes in PUVA- and DMBA-treated animals. Most interestingly, the originally dopa-positive melanocyte-free interbrick areas of the tail skin became covered by melanocytes in the DMBA, UVB radiation, and PUVA series. UVA radiation alone or acetone (the vehicle for 8-MOP) did not produce these results. In our experiments, which were terminated after a 8-week application of DMBA with UVB radiation, no tumor formation was observed (tables 2, 3; figs. 1-5).

On the electron microscopic level, all these treatments resulted in an increase in melanosome formation. In some instances these melanosomes were sequestered into secondary lysosomes within the melanocytes instead of being trans-

TABLE 2.—*Changes in melanocyte number of mouse tail epidermis after treatment with PUVA and UVA radiation*[a]

Treatment	Treatment duration	Mean No. of melanocytes/mm^2 ± SEM, SD[b]

ferred into keratinocytes. The melanosome structures, however, remained normal.

The covalent addition of psoralens as well as of some carcinogens to DNA is believed to be responsible for the inhibition of DNA synthesis in proliferating cells. Even now, nearly nothing is known about the mechanism of psoralen-induced melanogenesis. A few years ago we reported on the possible involvement of singlet oxygen in enzymatic and nonenzymatic melanin synthesis (*18*). It is known that psoralens under PUVA conditions can generate singlet oxygen (*19*). The relationship of this phenomenon to PUVA-induced melanogenesis, however, still needs to be established. Recently, we further extended our in vivo experiments by studying human melanocytes in cell cultures. These in vitro experiments (*20*) suggest that while UVB radiation is melanogenic, it can also be lethal. Pure cultures of human epidermal melanocytes were exposed to UVB radiation and were allowed to incorporate tritiated dopa (1.0 mCi/ml) from the growth medium for 48 hours. The single-exposure doses of UVB radiation were 0.1, 0.5, 10, and 50 $\mathrm{mJ \cdot cm^{-2}}$. The number of surviving melanocytes 48 hours after exposure was observed to decrease with increasing doses of UVB radiation. However, the incorporation of radiolabeled precursor (dopa) into melanocytes was found to increase at higher energy exposures. The highest dose tested, 50 $\mathrm{J \cdot cm^{-2}}$, resulted in a tenfold increase of dopa incorporation over control values. These results seem to be consistent with our previous findings, with the use of a retinal pigment cell culture system, that mitosis and melanogenesis are reciprocal cellular events. Possibly, UV radiation-induced melanogenesis is a specific instance of differentiation due to suppression of DNA synthesis (*21*).

DISCUSSION

This study has demonstrated that widely different factors when applied to melanocytes produce similar morphologic and functional results. In animals treated with UVB radiation, DMBA (with or without additional UVB radiation), and PUVA, the number of melanocytes and melanin production increased. UVB radiation and DMBA are known to be carcinogenic and seem to affect the melanocyte system in a very similar fashion. UVA radiation, which is not regarded as a carcinogen, did not increase the melanocyte number nor did it enhance melanogenesis to a noticeable degree. PUVA, however, produced results similar to those obtained with UVB radiation or DMBA treatment. One must also take into consideration the fact that UVA radiation delivers much less energy to the skin than UVB radiation. The difference in cellular response may be perhaps due not only to radiation spectrum but also to differences in the energy received by the skin.

The in vivo experiments reported here were done for only a short period and no tumor formation was observed. One should expand this investigation by studying the long-term effect of UVB radiation and DMBA and comparing their effect with that of PUVA. Furthermore, the effect of psoralen alone should also be studied.

In future experiments, one should also consider the observation made by Rosdahl (*22*) in regard to the possible systemic factors influencing melanogenesis in the entire melanocytic system following UV irradiation of a small area of the skin. Rosdahl observed that after exposure to UVB radiation, melanocytes increased in numbers both in a shielded area of the skin and in areas directly exposed to UVB radiation. This epoch-making observation indicates the existence of factor(s) controlling the mitotic cycle of melanocytes. It would be very important to know whether carcinogens or psoralens under PUVA conditions also exert their effect on remote areas of the integument by the same means.

In conclusion, from these studies a somewhat disturbing similarity emerges between the effects of UVB radiation and treatment by PUVA or by DMBA on mitotic division, melanogenic function, and morphology of melanocytes. The in vitro experiments indicate that UVB radiation can enhance melanogenesis and can be toxic at the same time. Great care should be exercised by physicians and by the general public, therefore, in regard to exposure to sun and the use of photosensitizers for cosmetic purposes.

Toxicologic Aspects of Photosensitization in Livestock[1]

A. Earl Johnson[2]

ABSTRACT—Two types of plant-caused photosensitizations are recognized in livestock: 1) primary, wherein the phototoxic agent in the plant is ingested and reaches the skin chemically unchanged; and 2) secondary, wherein the phototoxic agent is the porphyrin phylloerythrin produced by chlorophyll degradation in ruminant stomachs. Phylloerythrin is normally excreted in bile but is allowed to reach the skin when hepatic damage interferes with the phylloerythrin-excreting mechanism. Primary photosensitizing plant toxins are few, whereas secondary photosensitizations can be caused by damage to the liver by a variety of plant and other toxins. Plants causing each type of photosensitization are discussed and clinical manifestations of the disease in livestock are summarized. *Tetradymia* species are one of the most economically important causes of phototoxicity in livestock. The etiology of this phototoxic syndrome in sheep and the importance of sagebrush species as preconditioning agents for phototoxicity are discussed.—JNCI 1982; 69:253–258.

Photosensitization in livestock, though little publicized and often neglected by researchers, is a significant problem to livestock producers. It occurs in most classes of livestock in all areas of the United States and throughout the world. Just as humans are exposed to an ever-increasing number of toxic chemicals, livestock in their varied environments are at hazard with a multitude of insecticides, herbicides, fertilizers, and other chemicals that may contaminate their feed and water. These agents, however, often photosensitize only a few animals and generally give rise to single exposure or nonrecurrent situations wherein the overall economic impact to an individual livestockman or to a localized group of livestockmen is minimal. Thus these outbreaks have not justified extensive investigations, and often the etiologic relationships have not been fully understood.

Poisonous plants, however, have caused phototoxic reactions in livestock for many decades, and photosensitization in livestock is generally considered a poisonous plant problem. Thus most research has concentrated on the more economically important plant-induced photosensitizations. This presentation focuses on some of these plant phototoxicities to 1) describe the importance of photosensitization problems in livestock, 2) review phototoxic manifestations in livestock, and 3) report on some of the interesting etiologic aspects of one of the most serious photosensitization problems in sheep in the West.

CLASSIFICATION OF PLANT-INDUCED PHOTOTOXICITIES

The following is a classification of some of the common plants that cause photosensitization in livestock:

- Primary photosensitizers:
  - *Hypericum perforatum* (St.-John's-wort, Klamath weed)—contains hypericin, a naphthodianthrone derivative
  - *Fagopyrum sagittatum* (buckwheat)—contains fagopyrin, a naphthodianthrone derivative
  - *Cymopterus watsoni* (spring parsley)—contains furocoumarins
  - *Ammi majus* (bishop's-weed)—contains furocoumarins
- Secondary or hepatogenous photosensitizers:
  - *Tetradymia glabrata*—spineless horsebrush
  - *Tetradymia canescens*—gray horsebrush
  - *Agave lecheguilla*—lechuguilla
  - *Nolina texana*—sacahuiste
  - *Tribulus terrestris*—puncture vine
  - *Lantana* spp.—lantana
  - *Panicum* spp.—panic grasses (kleingrass)
  - *Brassica napus*—cultivated rape
  - *Senecio* spp.—contain toxic pyrrolizidine alkaloids
- Other photosensitizers:
  - Common feeds: *Avena* (oats), *Medicago* (alfalfa), and *Trifolium* (clovers)
  - *Sorghum vulgare* (sudan grass)
  - Blue-green algae
  - Fungi (moldy Bermuda grass, etc.)
  - *Polygonum* spp. (smartweeds)—closely related to buckwheat
  - *Euphorbia maculata* (milk purslane)
  - *Kochia scoparia* (summer cyprus)
  - *Bassia hyssopifolia*
  - *Vicia* spp. (vetches)

In *primary photosensitization* the phototoxic or photosensitizing agent is a component of the feed. As the ingested feed moves through the animal's digestive system, the agent withstands metabolism and excretion and is absorbed unchanged to reach the general circulation and thus the skin where it can react with light (*1*).

Of the primary photosensitizing plants just listed, St.-John's-wort (*Hypericum perforatum*) is best known (*2*). It occurs in the Pacific Coast States and throughout the Southern United States and may affect any class of livestock that eats it. St.-John's-wort contains hypericin, a naphthodianthrone derivative, as the phototoxic agent (*3*).

Bishop's-weed (*Ammi majus*) and spring parsley (*Cymopterus watsoni*) contain furocoumarins (*4, 5*). Bishop's-weed causes photosensitization in poultry (*6*). Spring parsley grows in areas of the Southwestern United States and causes sporadic problems in sheep. Spring parsely gives rise to a somewhat unique problem in that the udders of sheep that are nursing lambs become photosensitized. The udders are hyperemic, sore, and too painful for the sheep to allow their lambs to nurse (*7*). Large numbers of lambs on some range lands may thus die of starvation and dehydration.

Animals affected by primary photosensitizing plants can usually be saved if the cause of the problem is recognized and the animals are removed from the source of the phototoxic agent, penned in the shade, and treated with ointments and antibiotics to hasten healing and prevent secondary infection.

[2] Poisonous Plant Research Laboratory, Agricultural Research Service, U.S. Department of Agriculture, 1150 East 1400 North, Logan, Utah 84321.

In *secondary or hepatogenous photosensitization*, the phototoxic agent is phylloerythrin, a degradation product of chlorophyll (*8*). Phylloerythrin is produced in the stomach of ruminants by rumen microflora (*9*) and absorbed there into the bloodstream. In normal animals, phylloerythrin is eliminated in the bile and has no opportunity to be troublesome. Livers or biliary systems damaged in such a way that the phylloerythrin cannot be eliminated allow phylloerythrin to reach the skin where it reacts with light of appropriate wavelength as do other phototoxic agents. Any toxic plant or agent that causes interference with phylloerythrin excretion by the liver may cause secondary hepatogenous photosensitization if the animal is ingesting chlorophyll. Since chlorophyll is almost always present in the livestock diet, the true etiologic agent of such photosensitization is the hepatotoxic agent.

Secondary or hepatogenous photosensitizing plants cause most of the economically important losses in livestock because more than a phototoxic reaction is involved. Before photosensitization can occur, the damage to the phylloerythrin-excreting mechanism of the liver that must take place may be the result of subtle biochemical changes at the hepatocyte or membrane level or may involve more obvious intrahepatic biliary stasis. Ligation of the common bile duct (*10*) or cyst formation blocking this duct has shown that extrahepatic cholestasis also can generate hepatogenous photosensitization in ruminants on chlorophyll-rich diets. Furthermore, plants that cause cholestasis or blockage of phylloerythrin excretion often produce attendant and more serious hepatic damage and, indeed, some animals die from hepatotoxicity before photosensitization can develop. Thus secondary photosensitization often is less damaging than are the primary hepatic changes that give rise to it.

The *Tetradymia* species are perhaps the most economically important hepatogenous photosensitizing plants that I list and will be discussed in detail later. Lechuguilla and Sacahuiste are desert-type plants of southwestern United States and cause sporadic problems as do other plants in this group (*11*, *12*). Kleingrass causes photosensitization in lambs (*13*) but is not toxic to adult sheep and cattle. Several aspects of this condition are presently being studied, and it may develop that the etiology of this disease is not as straightforward as might be expected. *Senecio* species are not usually listed as photosensitizing plants, but this is due to the critical nature of the hepatotoxicity that develops before photosensitization is seen.

A third type of photosensitization, *congenital porphyria*, is sometimes seen in cattle, swine, and cats. It results from a genetic metabolic defect in the synthesis of the heme pigment ferroprotoporphyrin. Free protoporphyrin, uroporphyrin, and coproporphyrin accumulate in serum and tissue of these animals, which leads to photosensitization (*14*).

CLINICAL MANIFESTATIONS

Signs of photosensitization in livestock are similar regardless of the causative agent. Signs, of course, may vary in degree, depending on the amount of reactive pigment present in the skin at a given time, the amount of activating light of appropriate wavelength (or the degree of exposure to that light), and the degree and type of attendant hepatic damage, if hepatogenous photosensitization is being considered.

Animals with photosensitization first exhibit a restlessness and discomfort due to itching of affected skin parts. The affected skin areas are those least protected by dense wool, hair, or pigmentation. In sheep the lips, eyelids, and the head in general are most affected. Occasionally, the external genitalia may be affected if the tail has been docked too closely. The udder of both sheep and cattle may be photosensitized, and in cattle and horses any white or light-colored skin may be affected. The itching parts are scratched in any way the animal can manage—against fences, trees, rocks, or other animals. The animal may appear depressed. Erythema may or may not develop followed by edema of varying degrees. Edema of the head is particularly common in sheep. Ears and lips are first affected. Ears droop as they become swollen and heavy. The sheep has no control of its ears, which may hang pendulously. Swelling then occurs around the eyes and under the chin and the entire head may be much enlarged (fig. 1). The lay term given photosensitization in sheep involving edema of the head is "bighead" or "swellhead." Tissue disruption may follow with external serum leakage that gives rise to scab formation and secondary infection. In addition, in some sheep photosensitizations, the coronet of the hoof (*15*) and the base of the horns may become red.

Recovery may leave seriously affected sheep with barren patches of skin where wool will not grow. Some animals may be left blind because of scar tissue formation that covers the eyes (fig. 2). Lips may be similarly scarred, resulting in the sheep's inability to graze properly. Cattle and horses may lose patches of skin that slough in large, hard, leatherlike plaques, while adjacent black or darkly pigmented skin may be unaffected (fig. 3).

Livestock, though they often seek shade when phototoxicities are developing, cannot always find shade, or they may be fenced from it. Thus the period of exposure to sunlight may be long, resulting in much more severe photosensitizations than are commonly encountered in humans.

ETIOLOGIC STUDIES INVOLVING *TETRADYMIA GLABRATA*

Hepatogenous photosensitization as we have defined it is simple and straightforward and should be easily produced experimentally. This, however, is not the case in some plant-induced hepatogenous photosensitizations. Investigators working with *Tribulus*-induced (*16*), kleingrass-induced (Williams MC: Personal communication), and *Tetradymia*-induced (*17*) phototoxicities have found it difficult to induce phototoxic reactions experimentally in livestock, which indicates that other as yet unknown factors are important in the etiology of these syndromes. I have worked sporadically for many years with *Tetradymia* photosensitization in sheep and have found it to be a most interesting and frustrating problem. *Tetradymia glabrata* and *Tetradymia canescens* have been known to be toxic to sheep since 1922 (*18*) and to induce photosensitization in sheep since the 1930's (*19*), but attendant conditions important in the development of the toxic and phototoxic syndrome were not known. Outbreaks were sporadic and unpredictable and often economically devastating to livestockmen. Hundreds of sheep would be lost or affected in an individual herd at a single exposure. No further problems would be encountered for a few years and then another devastating outbreak would occur. The remainder of this presentation will acquaint you with this problem, perhaps give you an appreciation of some of the practical and economic aspects of livestock photosensitization as it happens in the field situation, and relate how we brought to light at least one etiologic agent important in this syndrome.

As background, you should have an appreciation of the land area and the management practices involved. Seventy percent of the land of Utah and adjacent Nevada is federally or state owned, so many sheepmen must graze their sheep on this land under a fee system. In summer sheep are grazed on National forest land in the Wasatch Mountains, a range of mountains that extends north and south through the center of Utah. In winter the sheep are grazed in semidesert areas south and west of the Great Salt Lake and into Nevada on land under the jurisdiction of the Bureau of Land Management. This desert land is lower and essentially free of snow in winter and consists of sparsely vegetated valleys interspersed at intervals of 5–20 miles with small mountain ranges. The land is essentially sagebrush range but contains enough desert-type plants to maintain sheep in winter and spring, if good management practices are employed.

A major problem is that these summer and winter ranges are 150–200 miles apart, and the sheep must therefore traverse this distance twice each year. Many sheepmen now truck their sheep, whereas others do not. Thus about 40,000–50,000 sheep are trailed twice each year 5 miles/day for a period of about 30–40 days each way. Much of this trail is in an extremely remote area—no stores, houses, ranches, or even paved roads for 50- to 100-mile stretches. When problems arise, the livestockmen must have the equipment, knowledge, and ingenuity to resolve them unaided.

Individual size of these trailing herds varies from a few hundred to 2,000 sheep. The possibilities for problems in herds of this size are unlimited as herders try to confine the sheep to a prescribed trail about a mile wide. Much of the trail follows the old Pony Express trail, and occasionally the trail narrows to one-fourth of a mile wide. Such is the case at Simpson Springs, a major Pony Express station and site of a small settlement of years ago. Through long years of use in this confined area around the spring, most of the vegetation has been replaced by *Tetradymia glabrata.* Inasmuch as most sheep must pass this spot, over the years literally thousands of sheep have died or become debilitated at this location from *Tetradymia*-related photosensitization and the attendant hepatic problems.

In the 1930's researchers found that the photosensitization and deaths were due to sheep ingesting *Tetradymia* (*19*). The sporadic poisonings were not fully understood, however, and these early investigators could cause only an occasional photosensitization in sheep by experimentally feeding the plant. These researchers did note that *Tetradymia glabrata* is one of the first desert plants to green in the spring, that it is active only 2–3 months, and that the new green buds that last only a short time are most readily eaten by sheep. They also noted that the most serious outbreaks of *Tetradymia* toxicity and photosensitization frequently followed spring rains or snowstorms and determined that sheep ate *Tetradymia* more freely at those times.

Thus as I became associated with the problem several years ago, much information from field outbreaks was available, but definitive information from experimental feedings was limited. My first efforts were to confirm that which was already reported and to establish toxicity levels by experimentally feeding sheep raised at our laboratory (*17*). These goals required several years because of the logistics of the problem and the fact that green *Tetradymia* is available for such a short time each year. At the expense of 40–50 sheep, we were able to determine the lethal dose under varying conditions; we monitored blood and histopathologic changes and became familiar with clinical symptoms, but we could not produce photosensitization. After we were assured that light conditions at the laboratory were the same as those at the desert area and after we unsuccessfully fed every conceivable combination of *Tetradymia* doses, animals were taken from our laboratory to the desert area for experimentation. Similar feeding efforts to produce photosensitization there were also unsuccessful.

The next effort was to take sheep from a desert herd and experimentally feed them *Tetradymia.* Of these sheep, 70% developed some degree of photosensitization; however, a similar experimental feeding the following year to confirm results was unsuccessful. The only controllable difference in the 2 years' experiments was that the sheep were taken from the herds at different locations on the range—locations that had different types of plant forage. Just prior to our getting them, sheep on one part of the range had been eating black sagebrush (*Artemisia nova*); sheep on the other range area had not been eating black sagebrush.

After experimental feedings to confirm this suspected sagebrush–*Tetradymia* relationship, we now know that black sagebrush, a good winter forage for sheep, preconditions sheep for the toxic action of the *Tetradymia.* Sheep that have not been eating black sagebrush for a few days can tolerate at least three times as much *Tetradymia* in their diet as those that have been eating black sagebrush just prior to their eating *Tetradymia.*

This small bit of information that took so much work to ferret out has the potential of saving hundreds of sheep annually. It is not the complete answer to the sporadic occurrence of *Tetradymia* toxicosis in sheep, for we cannot always produce a higher percentage of photosensitization in sheep preconditioned with black sagebrush (*20*). However, we are hopeful that further investigations into the relationship of toxic compounds in black sagebrush and *Tetradymia* may give us a better understanding of the etiology of this photosensitization and possibly other hepatogenous photosensitizations in livestock.

DISCUSSION

I. M. Asher: Could you speculate on the purpose of these photosensitizing agents to the plants themselves? Is it an evolutionary designed defense, or is it intrinsic to the plant unrelated to the photosensitizing effect of the agent?

A. E. Johnson: Are you speaking about the hepatogenous type of photosensitization?

Asher: Yes, what do the chemical agents do for the plants that contain them, and is what they do related to their ability to harm the animals that feed on such plants?

Johnson: As I said at the onset, hepatogenous photosensitization is a simple porphyrin type of photosensitization in that the phototoxic agent phylloerythrin is a breakdown product of chlorophyll. All sheep ingest chlorophyll, and the phylloerythrin that is produced from it is normally excreted in the bile. All you have to do, then, is to damage the liver in some way so that phylloerythrin is not excreted, and the very small amounts of phylloerythrin that reach the skin will cause this photosensitization. In fact, you can block phylloerythrin excretion by ligating the common bile duct and cause photosensitization this way when the animal is receiving chlorophyll in its diet.

Since this phototoxic reaction is secondary or incidental to the liver damage causing biliary stasis, it is not likely to relate to the plant's ability to harm those animals that feed upon it. In fact, most toxic agents in plants have not been shown to function in metabolic pathways in the plant. But even though their function is unknown, it is my belief that there is insufficient evidence to say that these toxins developed evolutionally in plants to harm animals that graze on them.

M. Pathak: I enjoyed this presentation very much and learned some things. The early work in this area was done by Professor C. Rimington of England, if you know about this, on the syndrome called geeldikkop.

But what interested me about the sagebrush story is that in desert areas around sagebrush, nothing seems to grow except sagebrush. It is not that other seeds are not able to germinate, but sagebrush produces very potent coumarin, as well as furocoumarin.

And if you extract the sagebrush, they do contain very highly fluorescent, phototoxic agents, some of which even induce reactions that have properties of a photoallergic type of reaction.

There is a plant called *Thamnosma montana* in the desert area; it has a furocoumarin that comes out in the root, preventing anything else from germinating. And that is the same thing with the sagebrush, I speculate. The fascinating thing is that the sagebrush has a photosensitizing agent which can actually cause a phototoxic reaction.

Johnson: Yes, I was very interested in those comments, and we have tried to cause photosensitization by feeding the sagebrush alone; however, we have been unsuccessful. We have not really delved into it, because there are many potential toxic agents in sagebrush, in addition to essential oils and sesquiterpene lactones.

K. Kraemer: You mentioned that the animals became sensitized by ingesting these plants. Do the levels of any of these sensitizers in the tissues in the milk or in the meat of the animals reach such concentrations that they would be dangerous to humans if they were to be ingested?

Johnson: No; that we are aware of. We cannot answer that question because we actually have not checked it out. But I would suspect not.

N. Salman: Is there any practical way to deal with the problem, to cover the sensitive parts of the sheep? I know that to study the plants and determine what type of photosensitizers they have is good, but is there meanwhile, any practical way, a quick way, to deal with the problem by maybe covering the sensitive parts of the sheep, for example, the head or any other vulnerable parts of the body, to overcome this serious and urgent problem?

Johnson: This, of course, if one of the problems of working with large numbers of animals. As I mentioned, we are talking about 2,000 sheep in some of these herds, and it is utterly impossible to cover that number. We have talked about protective compounds, carotenoids, tocopherol, and others, and there are some possibilities here that we need to investigate further; but even getting protective compounds into these sheep, under the conditions in which they are managed, is an extremely difficult thing to do.

Chemical and Biochemical Aspects of Photosensitization in Livestock and Poultry[1]

G. Wayne Ivie[2]

ABSTRACT—Certain synthetic and naturally occurring chemicals, particularly those found in some range plants, may interact with livestock and poultry in the presence of activating light to produce photosensitization. Such photosensitization may have serious implications for livestock producers as a result of causing reduced performance of and even death of affected animals. The mechanisms producing photosensitization in livestock and poultry are discussed in context with the chemical nature of major livestock photosensitizers. The possibility that photosensitizing agents for livestock may have toxicologic significance in humans consuming photoactive residues in meat or animal by-products is considered.—JNCI 1982; 69:259–262.

Livestock and poultry producers face many obstacles in their attempts to produce economically and profitably meat, edible animal by-products, and animal fibers. In addition to wide and often unpredictable fluctuations in production costs and market stability, animal disease and toxicity problems may be encountered that are often unanticipated but which may be devastating. Although many animal diseases may be dealt with quickly and effectively, either by prophylaxis or by prompt diagnosis and drug therapy, problems involving toxicants are generally more difficult to manage. This difficulty of management arises because causal agents in animal toxicoses are often difficult to define and effective treatment procedures are often lacking.

A wide variety of substances may interact with livestock and poultry, with toxicologic consequences. Among such substances are pesticides, animal drugs, and industrial chemicals. Certain natural products to which animals are exposed in the diet, particularly toxic range plants, are of special significance. While the nature of the toxic responses elicited by any one or combination of these toxic agents may vary greatly, depending on the mechanisms of action involved, this report will deal with only those agents known to elicit light-dependent toxicities in livestock and poultry.

MANIFESTATIONS OF PHOTOSENSITIZATION

Livestock.—From the perspective of the producer or veterinary diagnostician, livestock photosensitization can be defined as an abnormal blistering and peeling of skin due to increased sensitivity to sunlight. Although such a definition is overly simplistic and does not take into account all biochemical and physiologic ramifications of the syndrome, from a practical standpoint it is a workable and generally accurate description of photosensitization as normally observed in such animals as cattle, sheep, and horses. The lesions of photosensitization appear almost exclusively on light-skinned portions of animals not sufficiently protected from sunlight by the animal's coat or by anatomic location (eyelids, nose and muzzle, anus and vulva, udder and teats, and the coronary band of hooves and horns). Early acute reactions are, predictably, erythema and edema followed by blistering, scabbing, and peeling of the skin. In severely photosensitized animals, scarring, deformation (particularly of the ears), and blindness may be permanent effects (*1–3*).

Poultry.—In birds, photosensitization affects unfeathered or undowned portions of the body including the beak, ocular area, comb, wattles, and feet. Edema, blistering, and scabbing may be succeeded by blindness, sloughing of the comb and wattles, and deformation of the beak and feet. Deformities are particularly severe and often permanent in young birds photosensitized during active growth stages (*3–6*).

GENERAL MECHANISMS PRODUCING PHOTOSENSITIZATION

It is generally considered that livestock photosensitization can be classified into one of three categories depending upon the origin of the ultimate photosensitizing agent (*1, 2*). Some classifications include a fourth, "miscellaneous," category (*7*). In *primary* photosensitization, the photoactive chemical(s) arise from some source external to the animal, such as from a foodstuff. Once in the animal, these chemicals or their phototoxic metabolites reach the peripheral circulation where they absorb incident sunlight and transfer the absorbed energy to cellular components in such a manner that cellular damage results. *Hepatogenous* photosensitization occurs when exogenous chemicals or their metabolites, though not inherently phototoxic, cause hepatic damage that results in retention of photoactive bile pigments. Such pigments reach abnormally high concentrations in the peripheral circulation and, in the presence of sunlight, result in phototoxicity. *Congenital* photosensitizations in livestock are genetic disorders of porphyrin metabolism that result in unusually high concentrations of photoactive porphyrins or porphyrin precursors in the peripheral circulation. *Miscellaneous* syndromes of photosensitization represent those instances in which the etiology is unknown. Such photosensitizations are not hepatogenous because liver damage is not associated with the syndrome; they are not congenital because photosensitization is associated with some external source (such as a photosensitizing plant). Thus, of necessity, most if not all miscellaneous photosensitizers of an undefined type are probably primary photosensitizers in which the chemical nature of the photosensitizing agent is not known.

Primary Photosensitization

Relatively few agents have been shown to cause primary photosensitization in livestock and poultry. A schematic representation of how such agents interact with animals to elicit phototoxic responses is shown in text-figure 1. Structures of some primary photosensitizing chemicals are shown in text-figure 2. Hypericin, fagopyrin, and protofagopyrin are highly conjugated naphthodianthrone derivatives that are responsible for the photosensitizing action of *Hypericum* spp. and *Fagopyrum* spp. in cattle and sheep (*8, 9*). Psoralens (linear furocoumarins) are well-known potent photosensitizers when activated by near UV light, and they occur in a large number of plant species from several families. Psoralens have been shown to account for the photosensitizing actions of *Ammi majus* and *Cymopterus* spp. in both livestock and poultry (*10–13*). The synthetic drug phenothiazine, used as an anthelmintic in several livestock species, can result in photosensitization under certain circumstances. It is thought that an oxidative metabolite, phenothiazine sulfoxide, may be the major photosensitizing agent in phenothiazine phototoxicity (*1, 2*).

Hepatogenous Photosensitization

Most agents known to elicit photosensitization in ruminants appear to be of the hepatogenous type. The progression of the syndrome is presented schematically in text-figure 3. In typical cases, foodstuffs such as range plants or moldy forage grasses that contain hepatotoxic chemicals or their precursors are consumed by the animals, and the toxin(s) are absorbed and transported to the liver. Hepatotoxicity ensues, which may be manifested as severe damage to liver cells and/or occlusion of the bile ducts. Ultimately, normal biliary excretion mechanisms are circumvented and photoactive bile pigments accumulate in the blood at abnormally high levels.

The chlorophyll derivative phylloerythrin is apparently the major ultimate photosensitizer in hepatogenous photosensitization in ruminants (*1, 2, 9*), although other photoactive bile pigments may possibly be involved. Phylloerythrin is a normal metabolite of the anaerobic fermentation of chlorophyll in the rumen (text-fig. 4). Phylloerythrin is a potent photosensitizer, but because it is normally eliminated rapidly through the bile, it usually has no significant effects on the animal. In liver-damaged animals, however, phylloerythrin is not eliminated normally; it accumulates in the blood, and its occurrence in the peripheral circulation at levels as low as 0.1 µg/ml, in the presence of sunlight, is sufficient to induce photosensitization (*14*).

TEXT-FIGURE 2.—Structures of certain chemicals known to act as primary photosensitizers in livestock and/or poultry.

A number of agents are known to induce hepatogenous photosensitization in ruminants, on the basis of liver damage associated with photosensitivity, but the exact nature of the hepatotoxic chemicals is known in few cases. Two sources of such hepatotoxic chemicals are *Lantana* spp., which contain the hepatotoxins lantadene A and other closely related chemicals (*15*), and the fungus *Pithomyces chartarum*, a saprophyte of some forage plants, which contains the hepatotoxin sporidesmin (*16*) (text-fig. 5). It should be reemphasized that chemicals such as the lantadenes and sporidesmins are *hepatotoxic* and not inherently photoactive.

Hepatogenous photosensitization in ruminants has been associated almost exclusively with the consumption of certain forage plants, but it seems probable that in some cases metabolites of fungi or other micro-organisms associated with these plants may be the actual hepatotoxic agents involved. The occurrence of hepatogenous photosensitization in livestock is often sporadic, unpredictable, and difficult to reproduce experimentally. Further, hepatogenous photosensitivity is sometimes associated with very palatable and important forage plants including alfalfa and Bermuda grass (*8, 16*). These observations strongly suggest that in such cases the hepatotoxins associated with photosensitivity may not be normal constituents of the plant species themselves.

Congenital Photosensitization

Photosensitization associated with inherited disorders of porphyrin metabolism in livestock is known but is of little economic or practical significance in livestock production. Congenital protoporphyria occurs in cattle and swine, and the syndrome as observed in cattle may have importance as a human model of the disease (*17, 18*). In congenital pro-

toporphyria, phototoxicity is caused by elevated levels of photoactive protoporphyrin in blood, which result from genetic deficiencies in heme biosynthesis (text-fig. 6).

Poultry disorders known as "turkey blindness syndrome" and "light-induced avian glaucoma" may occur when birds are reared under *continuous* artificial light (*19–21*). The mechanisms involved in producing these disorders are apparently not clearly understood, but it seems doubtful that such disorders should be classified as congenital photosensitizations in the context considered here.

ECONOMIC CONSIDERATIONS

It is probably safe to say that photosensitization, when considered in the context of other livestock diseases and toxicities, is not a major economic problem in livestock production. Photosensitization tends to occur sporadically and infrequently and may affect only a limited number of animals within a given herd. Also, photosensitization does not *usually* result in mortality, thus rapid action on the part of the producer to remove affected animals from the source of the photosensitizing agent or to provide protection from sunlight often results in the animals' rapid and complete recovery. This is not to imply, however, that livestock photosensitization is of no significant economic importance, for such is clearly not the case. Photosensitized animals, particularly those affected by hepatogenous photosensitizers, can in fact be killed by the disease or by complications arising from it, and surviving animals may be permanently affected (with blindness, scarring, deformation) such that their market value is destroyed or greatly reduced. In addition, weight gains may be affected, milk production may be reduced, animals photosensitized on the udder and teats may refuse to nurse their young, and the stresses associated with photosensitization may result in abortions. Thus, in some instances, livestock photosensitization can and does have significant economic impact. The relatively widespread occurrence of "facial eczema" in New Zealand among diary cattle grazing forage that contains *P. chartarum* is an example of a livestock photosensitization syndrome that has considerable local economic impact (*16*).

In contrast to the economic effects attributable to photosensitization in livestock, essentially *no* economic effects result from poultry phototoxicities because photosensitization in poultry is rare except under experimental conditions. I am aware of only one circumstance in which domestic poultry have suffered severe nonexperimental photosensitization, and that was in Israel among pasture-raised ducks and geese that grazed the psoralen-containing weed *A. majus* (*22*). The rarity of photosensitization in poultry is understandable in view of production practices in which dietary regimens are usually carefully regulated and because much of the poultry production worldwide is done indoors under relatively low-intensity artificial light. However, photosensitization of domestic poultry reared under less intensive practices, particularly among free ranging-birds, probably occurs periodically because of the widespread occurrence of photosensitizing agents in nature and because of the generally omnivorous dietary habits of many avian species.

RESEARCH NEEDS

Photosensitization is at present not a major economic problem in livestock production, except in localized situations, but it seems appropriate to continue to develop research data that will allow a more complete understanding of these disorders in livestock and poultry. Further studies aimed at defining the chemistry of livestock photosensitizing agents and their biochemical modes of action could lead to the development of more accurate procedures for predicting photosensitization and possibly even effective antidotes or prophylaxes. Because the expressions of photochemical toxicities in food animals and humans are often identical or very similar, studies in livestock reasonably may be expected to generate data applicable to a more complete understanding of certain photochemical disorders in humans.

Photoactive agents that interact with food animals are often extremely active biologically, certainly as photosensitizers but perhaps also through mechanisms not dependent on light. Therefore, it may be that some photosensitizing

chemicals have direct toxicologic significance for humans, *if* these chemicals or their metabolites are retained by edible tissues or are secreted into milk or eggs. Such possibilities have thus far not been evaluated by suitable research approaches, although appropriate residue and metabolism studies with selected photosensitizers in food animals would provide data of considerable value toward an assessment of the toxicologic significance of these chemicals to humans.

DISCUSSION

Anonymous: I was requesting from the speaker knowledge of the exposure situation whereby livestock meet the phenothiazine molecule.

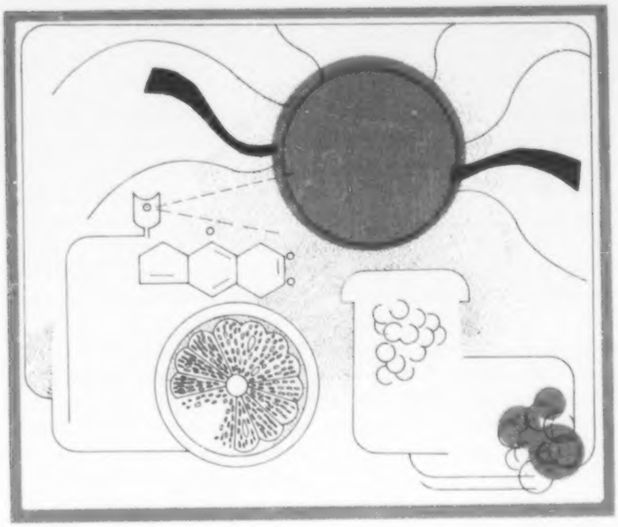
G. W. Ivie: Phenothiazine is an anthelmintic used to control intestinal parasites. Earl, is it given orally, by injection, or whatever? Do you know?

A. E. Johnson: Orally.

N. Towers: I want to make a comment about what Dr. M. Pathak said after the last talk. In *Artemisia*, the photosensitizing chemicals are polyacetylinic compounds and not furocoumarins. I thought I should make that statement, because the Compositae, which are the largest group of flowering plants, have this very large group of photosensitizers in them. These compounds have a totally different mechanism in terms of photosensitization in that they act on cell membranes rather than on the nucleic acids.

T. Nigra: This is a comment, perhaps about evolution, but nature seems to have provided for protection automatically, at least in terms of psoralens, when they are eaten. Herbivores are extremely difficult to photosensitize if you try to feed them drugs by mouth, whereas omnivores are much easier to sensitize, and the carnivores are easier yet.

I think it is very interesting that there seems to be some natural protective mechanism. If you look at serum levels of psoralen when you give the drug by mouth, the amount needed by mouth to produce phototoxic-inducing serum levels in the herbivores is markedly higher than the amount needed in the carnivores.



HUMAN PHOTOCHEMICAL TOXICITY EFFECTS

Chemical Phototoxicity in Humans[1,2]

John H. Epstein, *M.D.*[3,4]

ABSTRACT—Phototoxic reactions may be induced by endogenous or exogenous chemicals. Endogenous photosensitizers made by the body include porphyrin molecules which are responsible for the photocutaneous syndromes noted in the porphyrias. Exogenous photosensitizers may arrive on the skin through topical applications or may be distributed through the vasculature. Topical photosensitizers are found in cosmetics, medications, plants, and industrial and air pollutant emissions. Systemic photosensitizers consist primarily of therapeutic agents. Acute and chronic phototoxic reactions may occur. The acute response is generally characterized by erythema and edema followed by hyperpigmentation and desquamation. The end point of chronic damage may be cutaneous cancer formation. The mechanisms of these changes may well relate to nucleic acid injury, protein and membrane damage, and alterations in other nuclear and cytoplasmic molecular structures. However, translation of experimental information into human responses remains to be clarified. A great deal of investigation is still needed in developing assays for detecting phototoxic chemicals and for defining mechanisms involved in phototoxic events in human skin.—JNCI 1982; 69:265–268.

Injurious cutaneous photoreactions have become commonplace in the general population due *notably* to the sunbathing mania that pervades our society, but also due to the large quantities of photosensitizing chemicals being thrust into our environment from industrial, cosmetic, and pharmaceutical sources. The present report is concerned primarily with the last of these two conditions, i.e., the phototoxic effects of these chemicals on our collective skins.

LAWS AND DEFINITIONS

But before we examine the problems of photochemical toxicity in human skin, perhaps a brief discussion of certain basic concepts might be in order. Let us start with the basic law of photobiology. This law states that nonionizing radiation must be absorbed to produce a photochemical and thus the resultant photobiological reaction. This law then stipulates that the photosensitizer, chromophore, radiation absorber, or whatever term one wishes to use must be present at the time of radiation for a reaction to occur.

The action spectrum of a photochemical reaction and the resultant photobiological reaction consists of the wavelengths absorbed by a molecule which leads to a specific response. The action spectrum usually, but not always, simulates the absorption spectrum of a molecule. However, it must always be included in the absorption spectrum, since this radiation must be absorbed to produce a reaction.

"Photosensitivity" is the broad term used to connote adverse reactions to this radiation (*1*). Two types of reactions may occur: phototoxic or photoallergic. The phototoxic response can be divided into 2 subgroups: photodynamic and nonphotodynamic. Simplistically, the differentiation relates to the need of oxygen in the photodynamic process, though the process is much more complex (*2*).

Phototoxicity is common. It will occur in everybody if enough of the chromophore or photosensitizers are present in the skin. Clinically, the responses usually are comprised of a delayed erythema with or without edema, followed by hyperpigmentation and desquamation. Thus they resemble the ordinary UVB radiation (between 280 or 290 nm and 315 or 320 nm) sunburn response. In fact, the ordinary UVB sunburn is by far the most common phototoxic reaction that we see.

In contrast, photoallergy is uncommon (*3–5*). It is an acquired, altered reactivity, presumably dependent on an antigen–antibody or cell-mediated hypersensitivity. Clinically, it is characterized by unusual reactions. These reactions include immediate urticarial responses and delayed papular to eczematous lesions.

Almost all of the well-documented photobiological events that occur in the skin are induced by UVB radiation. Such radiation can inhibit DNA, RNA, and protein synthesis and mitosis formation, labilize lysosomal membranes, stimulate formation or release of vasoactive substances such as prostaglandins and kinins, induce a delayed erythema and new pigment formation, cause cancer, and produce vitamin D precursors in the epidermis. For practical purposes, this radiation does not pass through window glass. Thus a good sturdy piece of window glass will eliminate all of these cutaneous responses.

UVA radiation (315 or 320–400 nm) produces a few minor photobiological events such as immediate pigment darkening, due to photo-oxidation of melanin which is already present in the skin, and a transient immediate erythema response. However, UVA radiation is important to us for two reasons. UVA radiation markedly accentuates the injury produced by the UVB radiation and is responsible for the vast majority of exogenously photosensitized reactions that occur in the skin.

It is with this last issue (i.e., chemical phototoxicity) that this paper is concerned. Furthermore, this report is directed toward such a reaction in human skin. The initial consideration relates to the source and route of administration of these photosensitizing chemicals. The origin of these chemicals may be endogenous or exogenous.

ENDOGENOUS PHOTOSENSITIZERS

Only one type of photosensitizing chemical is made in the body (*6, 7*). That is, or more properly, these are the porphyrin molecules which are responsible for the clinical manifestations of the porphyrias listed below:

The porphyrias
- I. Erythropoietic
  - A. Congenital erythropoietic porphyria
  - B. Erythropoietic coproporphyria
- II. Erythrohepatic: Erythropoietic protoporphyria
- III. Hepatic
  - A. Acute intermittent porphyria
  - B. Porphyria cutanea tarda
  - C. Variegate porphyria
  - D. Hereditary coproporphyria
  - E. Acquired porphyria

As noted, abnormal amounts of porphyrins may be made in the hematopoietic system as occurs in the congenital erythropoietic porphyria of the Günther variety and erythropoietic coproporphyria, or they may be made in hematopoietic tissue and at times possibly the liver as well, as appears to occur in erythropoietic protoporphyria which may be a misnomer (*8*). Perhaps a more appropriate name would be erythrohepatic protoporphyria. The abnormal amounts of porphyrins may be made in the liver alone as occurs in acute intermittent porphyria, porphyria cutanea tarda, variegate porphyria, hereditary coproporphyria, and the truly acquired porphyrias.

All of these porphyrias have photocutaneous syndromes associated with them except one, i.e., acute intermittent porphyria. The reason for this is that all of these porphyrias except acute intermittent porphyria are characterized by the overproduction of photoactive, preformed porphyrins. In acute intermittent porphyria the porphyrin precursors δ-aminolevulenic acid and porphobilinogen are produced in excess. These reactions range from the marked photodestruction noted in congenital erythropoietic porphyria to the fragility, blistering, denudation, superficial scarring, crusting, and milium formation noted in porphyria cutanea tarda.

In all of these instances, the nature of the process is phototoxic. The action spectrum appears to peak around 400 nm, which is the peak absorption spectrum of the naturally occurring porphyrins in the human body, i.e., uroporphyrin, coproporphyrin, and protoporphyrin. This is a prime example of a photodynamic process that appears to involve the production of peroxides (*7*). These peroxides in turn labilize membranes, presumably lysosomal membranes, in the upper dermal blood vessel endothelium, which in turn results in the release of hydrolytic enzymes (*9–11*). The resultant responses appear to be responsible for the clinical pictures noted in these diseases. Recent evidence indicates that photoactivation of these porphyrins can result in activation of the classical pathway of the complement system with generation of chemotactic factors through C5 (*12, 13*). This process may well contribute to the photodamage that occurs in these diseases.

EXOGENOUS PHOTOSENSITIZERS

Exogenous chemical photosensitizers may arrive on the skin topically or systemically through the vascular system.

The topical exogenous photosensitizers may be placed in the following categories:

- I. Cosmetics: Perfumes, creams, soaps, etc.
- II. Medications
  - A. Advertent: Psoralens, tars
  - B. Inadvertent: Phenothiazines, sulfonamides, halogenated salicylanilides (and related compounds), sunscreens, etc.
- III. Plants: Gas plant, lime rinds, celery, carrots, etc.

Topical exogenous photosensitizers may be applied to the skin in the form of cosmetics, perfumes, moisturizing creams, soaps, and the like. Certain medications are applied to the skin, some of which are intended to produce photoreactions, e.g., the psoralen compounds and, occasionally, tar.

Other medications arrive on the skin without the intent to photosensitize. These include phenothiazines, sulfonamides, antibacterial agents such as the halogenated salicylanilides and related compounds, and sunscreens.

A number of plants contain photosensitizing chemicals, primarily psoralen compounds, which can and do induce photosensitive reactions. These plants include carrots, celery (especially celery infected with pink rot disease), gas plant, lime rinds, and the like. The primary photosensitizers in these plants are psoralen compounds, though other photosensitizers are found in other plants (*14*).

Industrial emissions constitute another source of topical photoactive chemicals. These agents are primarily polycyclic hydrocarbons that can act as photosensitizers or additive carcinogens (*2, 15*). In addition, potential promoters of photocarcinogenesis may be found in industrial emissions (*15*).

The commonly used systemic photosensitizers may be placed in the following categories:

- I. Antibacterial sulfonamides
- II. Thiazide diuretic medications
- III. Sulfonylurea antidiabetic medications
- IV. Phenothiazines
- V. Antibiotics: Especially demeclocycline

Photosensitizing chemicals that reach the skin through the vasculature are generally medications. The numbers of systemic photosensitizers are immense. They include potent photosensitizers such as the psoralen compounds that are usually employed to produce photoreactions to weak photosensitizers such as the antihistamine Benadryl. Included in our list of commonly used systemic photosensitizers are antibacterial sulfonamides and their relatives the thiazide diuretics and the sulfonylurea antidiabetic drugs. The phenothiazines, especially chlorpromazine and certain antibiotics, are also included in this group. More complete lists of potential topical and systemic photosensitizers are available (*16–18*).

CLINICAL REACTIONS

Acute phototoxic responses are by far the most common reactions to these agents. These responses are usually characterized by a delayed erythema and edema followed by hyperpigmentation and desquamation or peeling. If the chemical is applied to the skin, the epidermis may be severely damaged such as seen in topical psoralen photosensitization. In contrast, if the agent reaches the skin through the vasculature, the primary site of injury may be in the dermis with little or no visible epidermal change. In both instances the inflammatory cellular response is very slight in the dermis in human skin (*17*). This is similar to the lack of cellular infiltration noted in human cutaneous acute UVB sunburn reactions.

Certain exogenous chemicals such as tetracycline hydrochloride, nalidixic acid, and the sulfones can produce low-grade phototoxic injuries that are expressed as blistering, fragility, denudation, scarring, and milium formation (*19, 20*). These changes are identical (clinically and microscopically) with those found in a number of the porphyrias (*9*).

Photosensitization by certain exogenous chemicals in humans is primarily or exclusively photoallergic. These chemicals include the halogenated salicylanilides, musk ambrette, and 6-methylcoumarin (*21–24*).

Chronic actinic damage and skin cancer formation are induced primarily by the UVB rays from the sun. In general, this process in humans has not been associated with exogenous chemicals.

However, such a relationship with certain forms of photochemotherapy has recently been established. In a large series of psoriatic patients treated with psoralens and UVA radiation, Stern et al. (*25*) noted a definite increase in cutaneous cancer formation. This increase was even more clinically significant because the cancers were found primarily on parts of the body usually not chronically exposed to the sun (*25*). More recently, these authors reported an increased skin cancer incidence in psoriatic patients who had received very extensive treatments with coal tar and UVB radiation (the Goeckerman regimen) (*26*). This may represent an additive carcinogenic effect between the tar and UVB radiation energy, since the action spectrum for coal tar photosensitization is in the UVA radiation range.

Thus patients with psoriasis may be at increased risk of developing skin cancer because of certain treatment modalities in wide use at the present time. However, a greater portion of the population may be at risk, i.e., individuals exposed to industrial contaminants and a great deal of radiation from the sun such as oil field workers and the like (*17*). Also air pollutants, many of which are photosensitizers, might cause chronic phototoxicity. But perhaps more importantly, these last two sources may relate to photocarcinogenesis as additive carcinogens and/or promoters. Experimentally, the carcinogenic effects of the polycyclic hydrocarbon 7,12-dimethylbenz[*a*]anthracene have been shown to be additive with the cancer-producing properties of UV radiation (*27*). In addition, certain essentially noncarcinogenic agents will promote UV carcinogenesis in experimental animals (*17, 28–30*). Possibly, industrial contaminants and air pollutants that contain both carcinogens and promoters accelerate cutaneous cancer formation in human skin similar to the acceleration of cutaneous cancer formation noted experimentally.

MECHANISMS OF CHEMICAL PHOTOTOXICITY

Although chemically induced phototoxic reactions have been described, specific evidence of how these reactions occur in human skin is not available in most instances.

Photodynamic processes appear to be responsible for reactions to certain dyes, to polycyclic hydrocarbons, and as noted previously and perhaps most commonly to porphyrin molecules in the porphyrias (*6, 7*). In this last instance, the photodynamic reactions may lead to peroxide formation which in turn may labilize lysosomal membranes and thus release hydrolytic enzymes that would lead to further cellular damage (*7*). The available evidence indicates that this initial photoinjury occurs primarily in the upper dermal blood vessel endothelial cells (*9–11*). As noted, porphyrin photosensitization in serum can lead to activation of the classical complement pathway and generate chemotactic activity derived from C5 (*12, 13*). This may also add to the cutaneous changes noted in the porphyrias.

As pointed out in previous papers in this symposium, certain psoralen compounds intercalate into the DNA helix. On photoactivation with UVA radiation, monofunctional and bifunctional adducts may be formed in the DNA (*31, 32*), which may lead to inhibition of DNA synthesis, cell damage, and cell death. Photoreactions with proteins containing aromatic amino acids can also occur (*32*).

Photoinduced DNA cross-links have been reported with coal tar extracts and anthracene (*33*). Also, lysosomal labilization has been accomplished with anthracene as well as with porphyrins (*34*). How this injury translates into the erythema, edema, and eventual dense hyperpigmentation that we see morphologically remains to be determined.

The production of a toxic photoproduct can cause membrane damage and result morphologically in an erythematous cutaneous response. Recent evidence indicates photoreactions at least in part can be due to this type of mechanism (*35–37*). In general, much more information is needed to clarify the mechanisms leading to the changes that occur in and during chemically induced phototoxic cutaneous responses.

ASSAYS FOR PHOTOTOXIC CHEMICALS IN HUMANS

Agents capable of producing phototoxic effects have been identified by use of a variety of in vitro and in vivo systems. However, the ultimate issue concerns the effect these molecules have on human tissue in vivo (*38*). In general, the following four techniques have been utilized: systemic administration, topical application with occlusion, topical application after the stratum corneum is stripped off, and intradermal injection of the molecules. Each of these techniques has disadvantages, among which are lack of distribution to the skin of the active photosensitizing molecule, metabolism of the chemical to a nonphotosensitizing structure, lack of metabolism to an active photosensitizing structure, lack of penetration to the appropriate target tissue, lack of irradiation with the appropriate wavelengths, and lack of irradiation at the appropriate time. Thus any human assay may well miss the target.

Human Models for Identification of Photosensitizing Chemicals[1]

Albert M. Kligman, *M.D., Ph.D.,*[2] *and* **Kays H. Kaidbey,** *M.D.*[2]

ABSTRACT—The human is an appropriate and sensitive animal for identifying photosensitizing drugs administered either topically or systemically. Topically effective phototoxic agents are quite easily revealed when they are applied to normal or scarified skin which is subsequently exposed to 2×10^5 J·m^{-2} of near UV light (UVA, 320–400 nm). Systemically effective photoxic drugs can be identified by exposing intradermally injected sites to either solar-simulating or UVA radiation. Drugs that cause photocontact allergy can usually be recognized by irradiating pretreated sites six times over a 3-week period with a solar simulator and then challenging the sites with UVA. Existing models, the human model especially, should make it possible to recognize important photosensitizing drugs before they are marketed. JNCI 1982; 69:269–272.

It has long been known that, in the presence of light, certain chemicals can damage or kill many different kinds of cells such as bacteria, fungi, protozoa, and red blood cells, fibroblasts, and epidermal keratinocytes. That drugs can mediate abnormal reactions to sunlight in humans is relatively recent knowledge. The flood of new drugs introduced since midcentury has brought with it the painful awareness that very different kinds of molecules can induce abnormal light reactions through a number of mechanisms. We now know that photosensitizing chemicals abound in the environment, showing up in such diverse products as cosmetics, fragrances, soaps, household items, dyes (in bathing suits), sunscreens, topical medicaments, and drugs given orally or parenterally.

The inventory of chemically identified photosensitizers is large, numbering in the hundreds, and is diverse. Though most are aromatic compounds and very few are inorganic substances such as cadmium, their structures may be dissimilar. Except for congeners of well-known photosensitizers, the capacity of a new agent to provoke abnormal light reactions is impossible to predict by inspection of its molecular structure.

If in vitro models could be used to appraise photosensitizing potential, it would be ideal. In vitro techniques are quick, simple, and inexpensive, such as the one devised by Daniels (*1*) in which zones of inhibition develop around drug-impregnated paper disks placed on petri dish cultures of *Candida albicans* which have been irradiated. Regrettably, the killing of yeast cultures by light is relatively insensitive; some well-known photosensitizers are not detected by this screening technique. Other in vitro models in which cultured human lymphocytes or fibroblasts are used are not yet practical.

The crucial test for any model is whether it consistently identifies known photosensitizers. Too often, the test has high sensitivity for one class of chemicals, e.g., tetracyclines, but fails completely with sulfonamides. Potent photosensitizers such as the psoralens are quite easily recognized. (The Egyptians pioneered the field centuries ago.) Mild photosensitizers are often difficult to detect. Although we automatically think of photosensitizers as harmful, psoralens and coal tar have proved very beneficial in the photochemotherapy of psoriasis. Clearly, there are positive and negative medical implications, but here our main concern is adverse effects.

Animals should be used to an advantage in the detection of photosensitizers. Albino murine species should be ideal because they lack native photoprotection. Numerous attempts, most notably by Morikawa et al. (*2*), have been made to develop animal models. These workers compared photosensitizers in various species. Their experience typifies the problem. Some known photosensitizers were confirmed, but tetracyclines and sulfonamides were not. False-negative results for important photosensitizers are found in many animal models. This is true for the guinea pig ear model of Stott et al. (*3*) and for the hairless mouse model of Gloxhuber (*4*) and of others who used oral, ip, and topical applications.

Part of the difficulty is the uniqueness of human skin, which really has no true animal counterpart. For example, the vasculature of the murine species is sparse compared to the rich venular plexuses of the human. Accordingly, the inflammatory display, in which vessels are crucial, is greatly diminished in animals. This restriction lessens the likelihood of recognizing weak photosensitizers.

Very few photosensitizing drugs have been identified before their widespread clinical use. Only recently have appropriate tests been developed to meet the need for revealing photosensitizing potential before a drug is marketed. Unfortunately, inquiry into the possibility of photosensitization is still not routine in the development of systemic drugs.

PERSPECTIVES

The term "photosensitization" applies to chemicals that cause unusual reactions to sunlight. Two forms of photosensitization will be discussed here: phototoxicity and photoallergy. Theoretically, phototoxic responses can be elicited in all persons given enough drug and enough light, though susceptibility varies a great deal among individuals and races. Phototoxic chemicals give rise to a varied repertoire of skin lesions, ranging from wheals to acute dermatitis to bullae. Some damage cell membranes, others damage organelles, and still others interact with DNA. This diversity of expressions tells us not to depend on rigid routines such

[2] Duhring Laboratories, Department of Dermatology, University of Pennsylvania School of Medicine, Medical Education Building, 36th and Hamilton Walk, Philadelphia, Pa. 19104.

as single readings at some convenient interval such as 1 day, a traditional favorite. For example, if readings are made at 24 hours, one may miss wheals that develop shortly after irradiation but that fade in an hour or two. Likewise, phototoxic reactions to furocoumarins generally do not peak until 72 hours.

By contrast, photoallergic reactions do not show a diversity of clinical expressions and are set apart by being immunologically mediated. They are T-cell-dependent, delayed hypersensitivity responses akin to allergic contact dermatitis.

Phototoxic drugs outnumber photoallergic ones by a large margin. Most of the photoallergic drugs belong to a single class of compounds, i.e., the halogenated phenols. Their harmful effects are apparent after topical applications and are, therefore, examples of photocontact allergy. Bona fide instances of orally administered photoallergic drugs are quite rare and are not without diagnostic ambiguities. Chlorothiazide is probably the only unequivocal example and sulfonamides may perhaps sometimes qualify. Even a potent photocontact allergen like chlorpromazine very rarely causes photoallergic reactions when taken orally. Still, as clinicians, physicians must be forever watchful for the unexpected if diagnostic disasters are to be avoided.

Very few drugs are both phototoxic *and* photoallergic. 3,3′,4′,5-Tetrachlorsalicylanilide, an antibacterial that caused a famous epidemic of photocontact allergy, is the best example. It was initially thought that phototoxicity was a prerequisite for a chemical to be photoallergic. This was a mistaken idea, for the two are usually dissociated and have no common denominator. Each quality must be separately tested.

There are many examples of phototoxic chemicals that are capable of causing skin disease both when topically applied and when systemically administered. Phototoxic agents that are topically applied are the commonest, but orally administered ones are also important. Topical and oral agents are tested in different ways. The best known orally sensitizing phototoxic drugs are the tetracyclines and the phenothiazines. It is worth emphasizing that these drugs continue to be widely used, mainly because they are valuable therapeutic agents whose photoreactivity is well known to all. These orally administered drugs are not necessarily disqualified because they are phototoxic. This contrasts with topically sensitizing photoallergens whose uses are much less important. Besides there is a special urgency to identifying photocontact allergens, for once sensitized, the victim may be reactive to light for years after the last exposure. The plight of the persistent light reactor is a compelling reason why all new topical substances should be routinely examined for their capacity to induce photoallergy.

Once identified, topical phototoxic chemicals are best avoided. This precaution becomes especially important when a sunscreen ingredient turns out to be phototoxic. This actually happened in the case of the amyldimethylester of *p*-aminobenzoic acid, otherwise an effective absorber of UV radiation (*5*).

With the use of human skin tests, it is unlikely that significant phototoxic chemicals and drugs will not be detected by the laboratory screening procedures. We emphasize the value of the human model because human skin is plentiful, only a small test area is required, and the reactions are transient and easily borne. Furthermore, the findings are likely to be the most relevant.

LIGHT SOURCE

The professional tester must have an apparatus that emits a continuous spectrum of UV radiation covering the UVB (290–320 nm) and the UVA (320–400 nm) ranges and extending into the visible region. The xenon arc is the most versatile and most suitable of the available light sources. It produces high-intensity radiation which with appropriate filters can yield a spectrum resembling sunlight. Xenon solar simulators are now commercially available at reasonable cost. The action spectrum for the great majority of photosensitizing drugs, phototoxic and photoallergic, lies in the UVA region. With the Schott WG 345 filter, all xenon rays below 320 nm can be excluded; thus sunburning radiation is abolished and only UVA radiation and visible light remain. Visible light is important for certain photodynamic dyes such as the xanthene and anthraquinone dyes, which are activated by rays beyond 400 nm. IR radiation must be attenuated to avoid nonspecific or painful heating effects.

Though not common, certain orally effective phototoxic drugs are activated by UVB radiation, e.g., chlorothiazide. The solar simulator is quite suitable for such agents because concomitant exposure to UVA radiation is of no consequence and need not be filtered out. If desired, inexpensive radiometers are available for determining exposure levels. Alternatively, the amount of radiation may be expressed as the MED, that exposure just producing a uniform erythema in 24 hours.

IDENTIFICATION OF TOPICALLY EFFECTIVE PHOTOTOXIC CHEMICALS

Topical phototoxic chemicals can be evaluated by a relatively simple and straightforward procedure described previously from this laboratory (*6*). Nonirritating concentrations of the chemicals are applied to 2×2-cm areas of skin at a topical dose of 5 $\mu l/cm^2$. Soluble substances can be dissolved in ethanol or water at 1–2%, whereas insoluble material can be suspended at 5% in an oil and water cream such as hydrophilic ointment U.S.P. The skin site is covered by a nonabsorbing cotton cloth and an impermeable adhesive tape (blenderm) for 6 hours and is then exposed to xenon radiation with the sunburning rays filtered out. An appropriate light dose is $2\times10^5\ J\cdot m^{-2}$, which is generally less than that which will produce erythema on untanned white skin, with the exception of individuals who burn very easily. The threshold photoactivating dose may be and usually is very much lower, i.e., often $2\text{–}3\times10^4\ J\cdot m^{-2}$. Controls include a drug-treated unirradiated site and a vehicle-treated irradiated site.

The development of immediate abnormal reactions such as burning and stinging, erythema, wheal, and flare, which may occur during or within 5–10 minutes of exposure, is diagnostic of phototoxicity. Crude coal tar is the classic example. The burning is perceived first, and it may be nearly intolerable. Generally, the erythema and flare fade in an hour or so; 24 hours later, the exposure site shows a sunburn-type erythematous reaction. Most topically active phototoxic chemicals show only delayed sunburn-type reactions, generally beginning in about 8 hours and peaking at 24. These sunburn-type responses are certainly not sunburns in the strict sense. Histologically, they are quite different, lacking the telltale sunburn cells. The appearance of erythema can also be delayed for 48–72 hours after exposure, as when the furocoumarins are used. Blisters are the ultimate expression of psoralen phototoxicity.

A negative reaction does not enable one to conclude that the substance lacks phototoxic properties. One further test is necessary to account for those chemicals that bind strongly to the horny layer and thus do not penetrate the viable tissue where the photosensitivity reaction takes place. Xanthene dyes such as eosin and rose bengal are typical of this class. When eosin was widely used in lipsticks, severe lip dermatitis was common; yet eosin on normal skin is quite harmless in the presence of light. The necessary modification for eliciting the adverse reaction is to apply the dye to skin lightly scarified with a fine, 30-gauge needle. With the barrier breached, wheals can be provoked immediately, and erythema is delayed until 24–48 hours later. Once photosensitization has been demonstrated, more precise determinations can be secured; i.e., the threshold dose for provoking a given response such as a wheal and flare or a delayed "sunburn" can be examined. If desired, one can narrow down the activating wavelengths by using band-pass filters or better still monochromatic radiation. The UVA region is quite broad, and for particular chemicals certain portions within this range are more effective than others. Sometimes only a relatively narrow band comprises the action spectrum, as with the porphyrins (406 nm). As a rule, the absorption spectrum and the action spectrum of topically effective photosensitizers correspond rather well. The following agents produce demonstrable phototoxicity when they are applied topically to humans:

Essential oils, e.g., oil of bergamot, rue oil, lemon oil, lime oil
Synthetic fragrances, e.g., dimethylanthranilate, 7-methoxycoumarin
Sunscreens, e.g., amyldimethylaminobenzoate
Furocoumarins, e.g., 5-methoxypsoralen, trimethylpsoralen, 8-methoxypsoralen
Coal tar and coal tar products
Polycyclic hydrocarbons, e.g., anthracene, fluoranthene
Phenothiazines, e.g., chlorpromazine
Anthraquinone dyes, e.g., disperse blue
Xanthene dyes, e.g., eosin, rose bengal; activity demonstrable only in scarified skin
Thiazine dyes, e.g., methylene blue; activity demonstrable only in scarified skin

SYSTEMICALLY EFFECTIVE PHOTOTOXIC DRUGS

Therapeutic agents designed for oral and parenteral use can be screened for photosensitizing potential by injections id into untanned lower back skin (*7*). The procedure is simple and highly reliable. So far all known phototoxic drugs can be readily identified. Pretest injections of 0.1–0.3% of the drug in normal saline are made id, and thereby a nonirritating dose is found. Ideally, the drug should be solubilized, but this is often not necessary. With drugs like nalidixic acid and benoxaprofen, the injection of sonicated suspensions gives negative results. Usually, if an appropriate pH is chosen, solubilization can be obtained; the material can then be nearly neutralized. Either 0.05 or 0.1 ml of the material is injected id, and within 5–10 minutes the back skin is exposed to UV light.

Since systemic drugs can be activated by a wide range of wavelengths, exposures to solar-simulating radiation should be done first. This requires individual determination of the MED, after which injected sites receive 0.5 and 1.0 MED. Controls consist of saline-injected irradiated sites and drug-injected unirradiated sites.

Systemically effective phototoxic drugs can provoke immediate-type reactions similar to those of topically effective phototoxic chemicals. Subjective sensations such as burning, stinging, and pruritus developing during irradiation are an important clue. Most often, the drug-injected site will show an intensified, infiltrated erythema with variable edema at 24–48 hours. Threshold doses for a selected concentration can then be determined along with appropriate dose-response measurements. Discomfort is minimal because of the small size of the test area.

The results of intradermal testing should not be too narrowly interpreted. Substances may be found to yield phototoxic reactions at very low concentrations, and yet these same drugs taken orally only rarely cause photosensitivity. This is typical of the tetracyclines, of which only demeclocycline is a clinical photosensitizer of importance. Actually, after oral administration only small concentrations are present in the skin, and by the time the drug perfuses the skin, it may have been transformed into its nonphotosensitizing metabolites. Thus a positive intradermal result means only that the drug has the potential to photosensitize. Whether this potential is likely to be realized can be checked in volunteers who ingest the drug at double doses. Because the action spectrum is already known, the drug should be given for at least 3 days before the exposure, which will allow the level of drug in the skin to accumulate. Administration of 0.5 and 1.0 MED of either UVB or UVA radiation must be individually determined beforehand. Observations should be made shortly after exposure as well as at 24–28 hours. Determinants for activity of common phototoxic drugs are given in table 1.

TABLE 1.—*Phototoxicity from id-injected drugs in humans*

Substance	Injected dose, μg	Activating waveband
Sulfanilamide	500	UVB
Sulfapyridine	500	UVB
Vinblastine	0.2	UVB
Nalidixic acid	150	UVA
Griseofulvin	200	UVA
Chlorothiazide	250	UVB and UVA
Demeclocycline	200	UVA
Tetracycline base	200	UVA
Furosemide	500	UVA
Quinidine	250	UVA
Prochlorperazine	250	UVA
Chlorpromazine	100	UVA
Benoxaprofen	500	UVA

Intradermal testing furnishes an additional benefit in that it helps rule out drugs which have been declared photosensitizers in clinical reports but which in fact are not. A surprising number of drugs have been labeled photosensitizers and show up regularly in published lists; yet the evidence is often flimsy at best and is frequently unconvincing. One can, of course, become sunburned while taking any drug. We believe the following drugs are some examples of falsely identified phototoxic agents: estrogens, saccharin, chlordiazepoxide, and tolbutamide. Photosensitivity reactions attributed to oral antidiabetic agents by clinicians are therefore probably examples of photoallergy.

PHOTOCONTACT ALLERGENS

The photomaximization test is simply a modification of the maximization test for detecting ordinary contact sensitizers. The difference is that solar-simulating radiation is added during induction (*8*). In fact, photocontact allergy is similar in every respect to contact allergy except that UV radiation is required for both induction and elicitation. The procedure entails occlusive applications of drug at 5% in hydrophilic ointment U.S.P. with subsequent exposure to three MED of solar-simulating radiation. Six such exposures are given to the same site after the drug is freshly applied each time. At 10-14 days after the last induction exposure, the drug is applied at 1% to a fresh site for 24 hours which is then irradiated with $4\times10^4\ \mathrm{J\cdot m^{-2}}$ of filtered UVA radiation. The development of a vesicular or an infiltrated, spreading erythematous reaction in the irradiated site but not in the control, unirradiated drug-treated site signifies the development of photoallergic contact dermatitis.

This method has been successfully used to demonstrate the photosensitizing capacity of a group of halogenated salicylanilides, notably those that have produced outbreaks of photosensitivity in the past, as well as of other chemicals such as coumarin derivatives (table 2). Experience with this technique in humans is still limited. However, some substances which have occasionally produced photoallergic contact sensitization in humans are not recognized in the photomaximization assay. These presumably false-negative trials include 3,4′,5-tribromosalicylanilide uncontaminated by dibrominated derivatives that are potent photoallergens and the fragrance musk ambrette. Recently, using improved methods of induction in the guinea pig, Jordan (*9*) and Ichikawa et al. (*10*) have succeeded in inducing photocontact sensitization to musk ambrette as well as to 6-methylcoumarin; however, Mauer et al. (*11*) found 6-methylcoumarin to be inactive in the guinea pig. The improved techniques including the use of Freund's complete adjuvant and scarification of the skin appear to greatly enhance the sensitivity of the guinea pig model for the detection of photoallergic contact sensitizers. Species differences in sensitivity, however, may exist, and more information is needed in this regard.

TABLE 2.—*Photoallergic contact sensitization by the photomaximization test*

Substance	No. of photosensitized subjects, $n=25$	Substance	No. of photosensitized subjects, $n=25$
3,3′,4′,5-Tetrachlorosalicylanilide	8	Coumarin	0
3,4′,5-Tribromosalicylanilide (pure)	0	6-Methylcoumarin	15
3,4′,5-Tribromosalicylanilide (impure)	2	7-Methoxycoumarin	11
4,5-Dibromosalicylanilide	3	Hexahydrocoumarin	0
3,5-Dibromosalicylanilide	10	Isoeugenol	0
5-Monobromosalicylanilide	0	Musk ambrette	0
Bithionol	3	Chlorpromazine	6
3,4,4′-Trichlorocarbanilide	0	5-Fluorouracil	0
Hexachlorophene	0	Benzoyl peroxide	0
		p-Aminobenzoic acid	0
		Sodium Omadine	6
		Zinc Omadine	0

SUMMARY

Our present view is that the photomaximization test is sensitive enough to detect all potent photocontact allergens. Those such as musk ambrette which rarely sensitize humans or do so under special conditions, as in shaving, may escape detection. It may be that the guinea pig is the animal of choice for photocontact allergy.

On the basis of studies with coumarin and its derivatives in humans, it appears that photoallergenic activity may be greatly influenced by small changes in the structure of the molecule. Furthermore, although coumarin itself possesses little or no photosensitizing potential, it can elicit photosensitization reactions in subjects sensitized to more potent derivatives.

Therapeutic In Vivo Photochemistry: Photochemical Toxicity Studies in Humans[1,2]

John A. Parrish, *M.D.*[3]

ABSTRACT—Information obtained by studies of phototherapy and photochemotherapy is reviewed and some of the advantages and disadvantages of using in vivo photochemistry to treat disease are examined. Selective in vivo photochemistry is used to treat a variety of diseases. Study of the dosimetric aspects of these treatments and quantitative analysis of acute risks are instructive to individuals interested in photochemical toxicity in humans. Results from prospective short-term and long-term clinical trials are especially instructive because the model used is the intact living human. These studies provide important data about toxic, allergic, and carcinogenic aspects of photochemical toxicity, which could not be obtained in routine animal toxicity experiments. Work done to develop, explain, or improve these treatments also provides insight into molecular mechanisms of photon-induced cell injury and the sequelae of that injury.—JNCI 1982; 69:273–278.

Selective in vivo photochemical toxicity is used to treat a variety of diseases. Dosimetric aspects of these treatments, quantitative analysis of acute risks, and prospective studies of long-term effects are instructive to individuals interested in photochemical toxicity in humans. Clinical trials of various forms of phototherapy and photochemotherapy provide the largest animal phototoxicity studies, and the model used is the intact living human. These studies obtain important data about toxic, allergic, and carcinogenic aspects of photochemical toxicity, which could not be obtained in toxicity experiments. The basic science studies used to develop, explain, or improve these treatments provide insight into molecular mechanisms of photon-induced cell injury and the sequelae of that injury. This manuscript reviews some of the information obtained by studies of phototherapy and photochemotherapy and also examines some of the advantages and disadvantages of using in vivo photochemistry to treat disease.

Phototoxicity is a general term often used simply to describe cell injury or tissue alterations induced by nonionizing electromagnetic radiation with or without photosensitizing chemicals. Phototoxicity is toxicity induced by photons. The radiation most often considered is within the UV and visible ranges. This radiation has appropriate quantum energy to cause electronic excitation and subsequent alterations in cell chemistry which can be specific and can lead to major alteration in cell function or viability. Photon-induced cell injury can be by mechanisms other than photochemistry because absorbed energy affects vibrational or rotational modes recorded as heating of tissues. However, use of the term "*photochemical* toxicity" usually not only implies that the mechanism of photon-induced toxicity is via photochemistry but also means that an exogenous chromophore has been supplied to initiate or augment the reaction. The singular term "phototoxicity" has also been used with more specific meaning, but unfortunately the specific meaning varies. Some authors use the term only when identified chemical photosensitizers are involved; others use it only when no known photosensitizer is present.

In the context of describing in vivo chemical photosensitization, the term is also used to separate nonimmunologic (phototoxic) responses from those effects involving immune mechanisms (photoallergic). Phototoxicity is also used to describe acute or chronic, morphologic or histologic alterations of skin by UV or visible radiation with or without the addition of chemical photosensitizers. Therefore, when one uses the term "phototoxicity," it is best to define the term clearly, avoid using it, or use it only in a general way to mean cell injury or toxicity induced by photons.

OPTICAL AND DOSIMETRIC PROPERTIES OF SKIN AND BLOOD

All photobiologic responses of skin are influenced by the optical properties of the skin. These properties determine the dosimetry of optical radiation within the tissue. Radiation transmitted into skin and cutaneous blood vessels has an internal dosimetric depth profile because penetration of UV and visible radiation into soft tissue is very wavelength-dependent.

The first optical interaction occurs at the surface of the stratum corneum, where some fraction of the incident radiation is scattered backward (reflected), since the refractive index of stratum corneum ($n_D \simeq 1.55$) (*1*) is much different from that of air (1.00). Because it is well described by Fresnel's laws of reflection, this fraction is called regular reflectance, and it typically accounts for 5–7% of nearly perpendicularly incident radiation. The regular reflectance component is nearly constant for all optical wavelengths and is the same for normal black and normal white skin (*2*). Of the radiation that enters the skin, part is scattered back to the environment, part is absorbed in various layers, and part is transmitted inward to successive layers of cells until the energy of the incident beam has been dissipated (text-fig. 1). Remitted (returning back from the surface) radiation

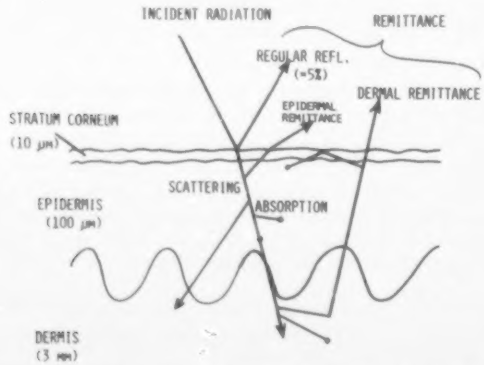
includes the regular reflectance from the surface plus that radiation which enters the skin and is subsequently backscattered outward. In the UVA (320–400 nm), visible, and NIR regions, most of the remittance of Caucasian skin is radiation which has traversed the epidermis, been backscattered by the dermis, and returned again through epidermis.

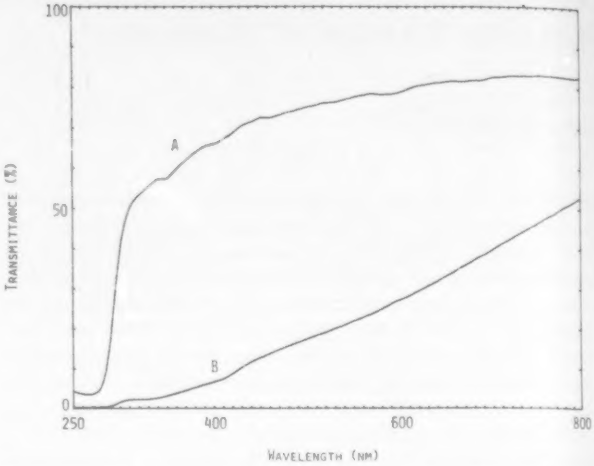
In the epidermis, aromatic amino acids both free and in protein, urocanic acid, nucleic acids, and melanin are the major absorbing chromophores. Transmission of Caucasian stratum corneum (text-fig. 2) closely resembles a solution of protein containing the aromatic amino acids tryptophan and tyrosine and having a minimum transmittance near 275 nm due to absorption by these and other aromatic chromophores (text-fig. 3). Nucleic acids, with an absorption maximum near 260 nm, and numerous small aromatic molecules, especially urocanic acid with an absorption maximum at 277 nm at pH 7.4, also contribute to the broad 275-nm absorption band seen in the epidermis and stratum corneum. Melanin content and distribution also play a major role in determining epidermal transmission. Across the UVA, visible, and NIR spectral regions, melanin is by far the most important epidermal chromophore, showing a smoothly declining absorption toward longer wavelengths out to 1,200 nm, a result of its highly conjugated, amorphic polymeric chromophoric backbone (text-fig. 3).

Optical scattering within the dermis largely determines the average path length and depth of penetration of radiation at various wavelengths. Dermal scattering is an inverse function of wavelength. The approximately 50% of UVA radiation which penetrates fair Caucasian epidermis is largely attenuated within the first 50 μm of the papillary dermis. However, a longer wavelength radiation such as 500 nm (green) may penetrate several hundred microns, and red and NIR radiation may penetrate several millimeters or more, or the entire thickness of the dermis. Another result of dermal scattering is that shorter wavelengths are remitted from the relatively more superficial layers of dermis, and these remitted rays experience, in general, a shorter average dermal path length than do longer wavelengths (table 1).

When the skin is irradiated in the UV and visible ranges, the blood and important components of the immune system are also being exposed. If one considers only metabolic need, the skin is highly overperfused. The mean blood flow to the skin is 20–30 times greater than the flow rate necessary for metabolic demands of the skin cells, and the maximum flow may be more than 100 times the minimum flow. This great variation of flow occurs largely because the cutaneous vascular system participates in the regulation of body temperature. The design of the cutaneous vascular system for temperature control is such that an unusually large portion of the blood is available near the surface of the body for exposure to nonionizing electromagnetic radiation.



TEXT-FIGURE 1.—Schematic diagram of optical pathways in skin. REFL.=reflectance.

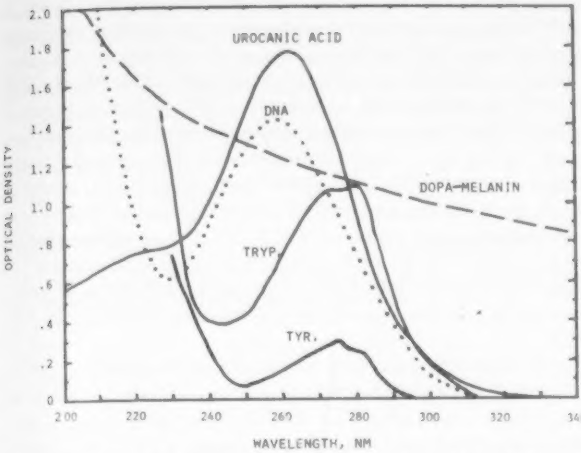


TEXT-FIGURE 2.—Human epidermis: transmittance from 250 to 800 nm. Surgical specimen was separated from dermis by being soaked in 60°C water for 30 sec and was mounted on integrating sphere in special container which allowed continuous wetting of basement membrane. A=fair Caucasian epidermis; B=black epidermis.

Skin blood flow has been measured by a variety of techniques. A nude subject at rest has an average cutaneous blood flow rate of 200–400 ml/m^2 body surface/minute (*3, 4*). This can be greatly increased, and flow rates up to 2,000 ml/m^2/minute have been reported (*5*). Flow varies from site to site, being greatest in digits and the face, especially the perioral areas. When cutaneous blood flow is accelerated, the skin blood content usually also increases, but these two parameters do not always run precisely parallel to one another.

Cutaneous blood flow accounts for about 10% of basal cardiac output; as much as 10% of the blood may be in the skin during any time period. This amount can be increased significantly by exercise or by inducing a heat load on the skin or host. At rest, an equivalent of the entire blood volume may pass through the skin two or more times during the time required for one minimal erythema dose (≈20 min) of sunlight. Much of this blood is exposed to UVA, visible, and NIR radiation.

The immune system is well represented in the skin with Langerhans' cells in the epidermis, mast cells and lymphocytes in the dermis, and other elements percolating through the lymphatics and capillaries of the dermis. All these components of the immune system are therefore exposed to environmental and therapeutic nonionizing radiation, and evidence is increasing that alterations of immune function



TEXT-FIGURE 3.—UV absorption spectra of the major epidermal chromophores at the following concentrations: 1.5 mg dopa-melanin/100 ml H_2O; 10^{-4} *M* urocanic acid/H_2O; 10 mg calf thumus DNA/100 ml H_2O (pH 4.5); 2×10^{-4} *M* tryptophan (TRYP.) (pH 7); and 2×10^{-4} *M* tyrosine (TYR.) (pH 7).

occur as a result of such exposure. Exposure of mice or guinea pigs to UV radiation results in a suppression of delayed hypersensitivity responses to contact allergens (*6, 7*) and injected hapten–protein conjugates (*8*). In rabbits, the rejection of full-thickness skin grafts is delayed by treatment with PUVA (*9*). The rejection of antigenic UVB radiation (280–320 nm)-induced skin tumors in mice is prevented by exposures to UV radiation; the mechanism appears to involve the generation of specific suppressor lymphocytes (*10*). In normal human volunteers, single exposures to erythemogenic doses of UVB radiation or PUVA produce an alteration in the distribution and function of subpopulations of circulating lymphocytes (*11, 12*).

PHOTOTHERAPY AND PHOTOCHEMOTHERAPY: IN VIVO THERAPEUTIC PHOTOCHEMISTRY

Phototoxicity is a likely mechanism for several forms of phototherapy and photochemotherapy. The use of photons as therapeutic agents has the advantage of selectivity of site (exposed skin) and depth of effect (wavelength-dependent dosimetric depth profile). Photochemical effects can also be quite selective, affecting specific chromophores within tissue or cells but not affecting adjacent molecules. In complex tissues, the possibilities for significant selective effects far exceed those available in which biochemical reactions are conventionally thermally accelerated. Nevertheless, the disadvantages of phototherapy and photochemotherapy involve unwanted acute and chronic phototoxic side effects. Definition and quantification of these unwarranted effects give massive information about photochemical toxicity in human tissues.

With some qualitative and quantitative differences, the cellular alterations and cascade of events known to occur in normal skin that has been UV irradiated most likely also occur in diseased skin that has been similarly treated. The differences in response may lead to improvement of diseased skin without irreversible or unacceptable damage to normal skin. For example, UV irradiation may decrease abnormal hyperproliferation or may interfere with function or viability of abnormal cells intricately involved in expression of skin disease. In some cases of skin diseases, abnormal cells associated with the diseases may be more sensitive to radiation than are normal cells. Paradoxically, certain photodermatoses can be improved by controlled exposures to UV or visible radiation. Phototherapy and photochemotherapy of photodermatoses may induce melanogenesis or injure cells involved in the pathogenesis of the photosensitivity. In polymorphic light eruption for instance, it is likely that both of these mechanisms are involved (*13*). Radiation may be cytotoxic to lymphocytes necessary to support the disease process, and UV radiation-induced delayed melanogenesis and thickening of the epidermis provide photoprotection. Lymphocytotoxicity may also operate in successful PUVA therapy of mycosis fungoides (*14*), lichen planus (*15*), or vitiligo (*16*).

Phototoxicity is probably also the therapeutic basis of the treatment of psoriasis with UV radiation. The exact therapeutic mechanism is unknown. It is assumed that photons must reach the proliferative compartment, and DNA is thought to be an important therapeutic target because psoriasis is a hyperproliferative disease. UV radiation temporarily decreases DNA synthesis in normal skin, and other agents known to be effective in psoriasis, including tar, affect DNA. Other potential mechanisms include preferential lethal effects on abnormal cells, inhibition of cell recruitment, gene effects, effects on dermal blood vessels, inhibition or killing of leukocytes, or photoimmunologic effects. Repeated exposures at phototoxic doses are required.

The mechanism of action of some forms of phototherapy appears to be direct photochemical alteration of extracellular chemicals present in skin and blood. Generalized pruritus, a common symptom of chronic renal failure, has been reported to be diminished by six to eight exposures of erythemogenic doses of UVB radiation (*17*). In patients with uremic pruritus, phototherapy of one side of the body results in generalized improvement, and the beneficial effect is not limited to only the exposed side. This observation suggests that the therapeutic effects may result from photoinactivation of a pruritus-producing circulating substance present in uremia (*18*).

Direct in situ intracutaneous extracellular photochemistry also seems the most likely mechanism in phototherapy of hyperbilirubinemia. In this disorder an insoluble form of bilirubin accumulates in tissues and may cause discoloration

TABLE 1.—*Penetration of radiation in fair Caucasian skin*[a]

Wavelength, nm	Depth, μm
350	60
400	90
450	150
500	230
600	550
700	750
800	1,200

[a] Approximate depth of penetration is one-third (37%) of the incident energy density.

(jaundice) of skin and permanent damage to the central nervous system. Photoisomerization of unconjugated bilirubin results in a more water-soluble form which can apparently pass directly into the bile (*19*). This photoisomerization and subsequent water solubility of bilirubin lead to reduced tissue levels of bilirubin and may prevent brain injury.

Photochemotherapy is the use of a chemical plus subsequent nonionizing electromagnetic radiation to achieve a therapeutic benefit. An exogenous chromophore or photosensitizer is added in an attempt to influence the site and nature of the photochemistry and subsequent photobiologic effects. Usually, in the doses used, the chemical alone or the radiation alone has no significant biologic effect. The chemical component of photochemotherapy may be given topically or parenterally, but it must reach viable cells which absorb subsequent radiation. Four major therapeutic regimens claim to use this form of in vivo photochemistry: 1) The Goeckerman regimen was conceived to be augmented phototherapy, i.e., topically photosensitized with crude coal tar, but this treatment as used today appears to be mainly UVB radiation phototherapy. The topical vehicle used to apply the tar alters the optical properties of the surface of the psoriatic tissue and thereby increases its transmission of UV radiation. It is unlikely that chemical photosensitization by tar plays a major role in the Goeckerman treatment as commonly used (*20*). 2) "Dye-light" treatment of recurrent herpes simplex with neutral red or proflavine and subsequent UVA or visible light radiation has not proved to be an effective therapy (*21*). 3) Another example of photochemotherapy is hematoporphyrin-visible light therapy of human cancer (*22*). This therapy, also called photoradiation therapy, has been successfully used to selectively destroy a certain cancer metastatic to skin. The future applications of this treatment are not certain at present. 4) PUVA therapy was discovered thousands of years ago and remains the best example of successful photochemotherapy.

For PUVA therapy and UV radiation phototherapy, in which phototoxicity is the most likely central therapeutic mechanism, the lists of potential long-term side effects are similar. However, there are major differences between these two methods of using photons to injure or alter cells. These differences are instructive to individuals considering chemical phototoxicity of human tissue. The depth profiles and average depth of in vivo photochemistry are different for PUVA therapy and UVB radiation phototherapy. Psoralen-DNA photoproducts and psoralen-UVA radiation-induced cross-links are quite different from UVB radiation-induced changes in DNA. They most likely have different effects on cells and are repaired differently. The most stable, easily isolated, and most studied photoproduct of DNA irradiation by UVB is the pyrimidine dimer. Other photoproducts also occur, but cross-links are very rare. PUVA therapy may be more lethal to certain cells or may be more effective as a mutagen because the resultant monofunctional or bifunctional photoadducts may be repaired by pathways different from the major DNA repair pathways that have evolved to restore the more usual DNA photoproducts. Monofunctional psoralen-DNA photoadducts may lead to a frameshift type of mutation. However, cross-linking may be less mutagenic than frameshifts in absolute terms because cross-linking is a more lethal event. A smaller surviving fraction may in effect display fewer mutations.

The non-DNA mechanisms of cell phototoxicity also differ, but less is known about in vivo UV radiation-induced protein, RNA, or membrane lesions. For example, whereas both PUVA (*23*) and UVB (*24*) are known to decrease viability and function of human peripheral blood lymphocytes, the relative mechanisms of their phototoxicities are at least qualitatively different. For UVB, trypan blue exclusion (most likely a membrane function) is diminished at lower doses than required to diminish phytohemagglutinin-induced blastogenic response. The reverse is true for PUVA (*24*).

The inflammatory response induced by PUVA differs from that induced by UVB. Prostaglandins are associated with the initial portion of the UVB-induced delayed erythema. Indirect evidence to date suggests that this prostaglandin involvement does not seem to be true for PUVA (*25*). Generalized symptomatic UVB-induced erythema is accompanied by a polymorphonuclear leukocytosis, which is not seen with PUVA (*26*). Delayed erythema after sufficient UVB radiation exposure begins after a latent period of a few hours and peaks at 12–24 hours. After PUVA, erythema usually does not begin for 24 hours and peaks at 48–96 hours. The erythema dose-response curve is more steep with PUVA than with UVB. Histologic studies show that in normal skin PUVA has more effect on blood vessels and that epidermal alterations last much longer (*27*).

The importance of these differences is not known. Both agents are known photocarcinogens, and both are expected to add to cumulative actinic insult of skin. Both are lymphocytotoxic with potential long-term effects. The greater depth effect and affected tissue volume of in vivo photochemistry may explain why several studies have found PUVA therapy to be more rapidly effective than UVB radiation phototherapy in some patients with psoriasis and why topical lubricants enhance the therapeutic effect of PUVA therapy less than they enhance the effect of UVB radiation phototherapy. However, PUVA therapy may be more likely to cause irreversible actinic changes because of its greater percentage of dermal effects. The viability and function of lymphocytes or other cells in the dermis may be more easily affected by PUVA therapy, and thus therapeutic or nontherapeutic effects may be increased. The best example of a qualitatively different risk associated with the two treatments is the primary eye hazard. Unintentional overexposure to UVB radiation causes an acutely symptomatic photokeratitis, which is usually reversible (*28*). The major risk to the unprotected eye of the patient receiving PUVA therapy is the development of cataract (*29*), a permanent decrease in visual acuity whose onset and maturity may be delayed for years to decades.

THE FUTURE OF THERAPEUTIC IN VIVO PHOTOCHEMISTRY

Advances in optics technology and the science of photobiology make it possible to think beyond therapy that depends on direct photochemical alteration of metabolites or on direct phototoxic insult to cells. Another generation of photomedical therapy will include in vivo photoactivation of medicines, photon-dependent drug delivery, and creative manipulation of host and exposure source to maximize therapeutic index (*30*). Clinical trials of these treatments will provide much additional information about photochemical toxicity in humans.

DISCUSSION

K. Kraemer: That was a very nice review of the current status of photomedicine. I would like to clarify one point: On theoretical grounds, if you were to manipulate the various factors and want to increase the radiant exposure to circulating cells in the skin, what you really need to do is to increase the volume of blood that is in the skin at a given time. If you just increase the flow rate, all that will mean is that the cells go through the skin faster. So at first approximation, it would mean that you would actually have less exposure to the circulating cells. Again, I request, if anyone knows of measurements of cutaneous blood volume in humans, this would be a very important factor to take into consideration. Then, if we manipulate skin blood volume, we can directly see what changes are induced.

J. A. Parrish: That is a very good point. There does not necessarily have to be a one-to-one correlation between increased flow and increased volume. I think, however, that anything that makes the skin subsequently red most likely has increased blood volume as well as increased flow, because your eye is telling you that there is more blood present there. By the time the photons scatter back to your eye, the blood has, of course, not travelled far. The photons travel much faster (186,000 mile/sec) than the blood flowing through the skin. So I think that the fact that you see the skin is red means that more than likely there is more blood present.

Also, there are a variety of ways to change the permeability of vessels, which may be more important than changing flow or content, because then you can release more substance into the tissue and subsequently photoactivate it. In summary, you are correct that we cannot assume that increased blood flow has a one-to-one correlation with increased blood content at any one time, because that may not necessarily be the same. There is inadequate information about this topic.

Photosensitization by Porphyrins and Prevention of Photosensitization by Carotenoids[1]

Micheline M. Mathews-Roth[2, 3]

ABSTRACT—Photosensitization by porphyrins and the use of carotenoid pigments as protective agents against photosensitization are examined. The use of carotenoids in the treatment of erythropoietic protoporphyria as well as other diseases of photosensitivity is reviewed. Possible mechanisms for the protective action of carotenoids are mentioned.—JNCI 1982; 69:279–285.

Photosensitization can occur not only from the ingestion or the topical application of a photosensitizing compound, but in some diseases it can occur from the endogenous formation of a photosensitizer. Examples of powerful endogenous photosensitizers in human disease are the various porphyrin compounds produced as a result of the metabolic defects in the photosensitive porphyrias (table 1). In these diseases, the presence of the abnormal porphyrins in the blood and skin results in the production of photosensitivity reactions, such as itching, redness, swelling, and formation of various lesions in skin exposed to light.

A "porphyric state" leading to photosensitization as well as other skin changes can be induced in otherwise healthy individuals by the ingestion of certain chemicals. An example of this was the accidental ingestion of the fungicide hexachlorobenzene by several thousand individuals in Turkey, where the chemical was used as a herbicide on the wheat crop. This compound caused a porphyria cutanea tarda-like syndrome. Most of the people afflicted continued to excrete abnormally high levels of porphyrins and experience photosensitivity for several years after hexachlorobenzene ingestion. Some of the characteristic skin changes of porphyria cutanea tarda, such as hypertrichosis and hyperpigmentation, persisted for many years longer. Additional examples of photosensitive porphyria-inducing chemicals in man and experimental animals, and more detailed descriptions of the various porphyrias, were reviewed by Meyer and Schmid (*1*).

Recently, the use of iv-administered hematoporphyrin and light exposure to delineate or treat human cancers has been introduced. This treatment renders the patients who received the hematoporphyrin extremely photosensitive for several months; casual exposure of unprotected skin to the sun results in the development of severe erythema, edema, and/or papule formation (*2*). This mode of therapy is still experimental, but if it proves successful, rigorous safeguards for protecting patients against photosensitization obviously will have to be developed.

What are the available means for protection against photosensitization by porphyrins? In the case of drug-induced porphyric states, avoidance of the drug is obvious. Also obvious is the instruction for patients to avoid unnecessary sun exposure and, when patients must go out, to shield the skin with appropriate clothing. The sunscreens that are effective against sunburn are ineffective in the case of the porphyrias. Opaque sunscreens, such as those made with titanium dioxide or zinc oxide provide some protection, but in most cases, patients find them cosmetically unacceptable.

A possible approach to the treatment of diseases with sensitivity to visible light such as the porphyrias was suggested from work on photosensitization and photoprotection in bacteria and plants. Sistrom et al. (*3*) found that the carotenoid pigments of the photosynthetic bacterium *Rhodopseudomonas spheroides* could protect these bacteria against lethal photosensitization by their own chlorophyll. These workers found that when a mutant of this organism, which could not synthesize colored carotenoids, was grown in the presence of light and air, growth stopped, chlorophyll was destroyed, and the cells were killed. However, the wild type, with its carotenoid pigments, was not injured by growth in light and air.

These workers further demonstrated that the bacteriochlorophyll was responsible for the lethal photo-oxidation of the blue-green mutant and that both oxygen and light were necessary for the destructive reaction. The carotenoid pigments of the organism were functioning as protective agents against this killing, and the bacteriochlorophyll was the photosensitizer responsible for the lethal photosensitization.

Many nonphotosynthetic bacteria also have carotenoid pigments. These organisms do not contain large amounts of potential photosensitizers as do the photosynthetic bacteria with their ample supply of chlorophyll. Nonphotosynthetic bacteria do contain small amounts of compounds such as porphyrins and flavins that can cause photosensitization. Sistrom and I (*4*) studied the wild-type and a colorless mutant of the nonphotosynthetic bacterium *Sarcina lutea* and found that in this organism also, the carotenoids of the wild-type were protective against lethal photosensitization. The pigments protected the organism against photosensitization by photosensitizers added to the medium, as well as against sensitizers naturally present within the cell. The ability of carotenoid pigments to protect against lethal photosensiti-

TABLE 1.—*Photosensitive porphyrias*

Disease	Biochemical lesion
Congenital porphyria (Günther's disease)	Functional imbalance between uroporphyrinogen I synthetase and uroporphyrinogen III cosynthetase. Elevated levels of uroporphyrin I and coproporphyrin I in erythrocytes, plasma, stool, and urine.
Erythropoietic protoporphyria	Partial deficiency of ferrochelatase. Elevated levels of protoporphyrin and often coproporphyrin in erythrocytes, plasma, and stool. Urine levels normal.
Porphyria cutanea tarda	Partial deficiency of uroporphyrinogen decarboxylase. Uroporphyrin and coproporphyrin in urine, occasionally in stool. Erythrocyte levels normal.
Variegate porphyria	Enzymatic lesion not definitely established. Elevated levels of protoporphyrin and coproporphyrin in feces, often also in urine. Erythrocyte levels normal.
Hereditary coproporphyria	Partial deficiency of coproporphyrinogen oxidase. Elevated levels of coproporphyrin in feces and to a lesser degree in urine. Erythrocyte levels normal.

zation has now been demonstrated in many other bacteria, both photosynthetic and nonphotosynthetic and also in green plants (*5*).

Lethal photosensitization can be induced also in mammals by the administration of hematoporphyrin and exposure to strong light (*6*). Because of the striking protective action of carotenoids in bacteria and in plants, it seemed possible that carotenoids might prevent this lethal effect also. To test this possibility, mice were given 1 mg of hematoporphyrin ip before exposure to strong visible light. Half of the animals had received 3 mg of β-carotene ip 18–24 hours before receiving the injection of hematoporphyrin and being exposed to light. Significantly more animals that received the β-carotene survived the treatment with hematoporphyrin and light than did those mice that had not received the β-carotene (table 2). Controls showed that the vehicle in which the β-carotene was suspended, a mixture of Tween-80 and saline, offered no protection against photosensitization and that control animals given either β-carotene or hematoporphyrin survived well if kept in the dark. Thus β-carotene was effective in preventing the lethal photosensitization of mice induced by the injection of hematoporphyrin and exposure to visible light (*7*).

From the results of the studies in bacteria and in animals, it now seemed feasible, because of the lack of toxicity of carotenoids in man, to administer β-carotene to patients with photosensitivity. The disease chosen for study was EPP. Patients with this abnormality of porphyrin metabolism complain of itching, burning, redness, and swelling of the skin exposed to the sun (*1*). Erythrocyte, plasma, and stool protoporphyrin levels are increased, but urine porphyrin levels are within normal limits (table 1). Typical lesions may be induced by exposure of the patients' skin to sunlight or to strong artificial light (e.g., xenon arc filtered to transmit light from 380 to 600 nm) under controlled conditions in the laboratory.

Could carotenoid pigments, which can protect against the photosensitization induced by the porphyrin group of chlorophyll, also protect against the photosensitization induced by the porphyrin group of protoporphyrin? In collaboration with Dr. Edward H. Kass, Dr. Madhu Pathak, and Dr. Thomas B. Fitzpatrick, Harvard Medical School and Massachusetts General Hospital, and Dr. Leonard C. Harber, Columbia College of Physicians and Surgeons, we treated with β-carotene (15–90 mg/day) 3 patients with EPP, each of whom had elevated erythrocyte, plasma, and stool protoporphyrin levels. All 3 patients, a 10-year-old girl, her 39-year-old father, and an unrelated 35-year-old man, showed marked improvement in their ability to tolerate exposure to sunlight, as well as an increased ability to tolerate exposure to a xenon arc lamp (phototesting) after they had taken β-carotene for 4–6 weeks. Protection continued as long as β-carotene was taken; when the medication was stopped, photosensitivity returned (*8*, *9*).

TABLE 2.—*Protective effect of β-carotene on photosensitization of mice by hematoporphyrin and visible light*[a]

Treatment	Light exposure	No. of animals	No. of dead animals	No. of animals alive
Hematoporphyrin[b]	Yes	27	21	6
Hematoporphyrin and carotene[b, c]	Yes	27	9	18
Hematoporphyrin and Tween 80–saline[b]	Yes	8	7	1
Hematoporphyrin[b]	No	8	0	8
Carotene[c]	No	8	0	8

[a] Data taken from (*7*).

[b] Animals received 1 mg ip before exposure to light.

[c] Carotene was suspended in Tween 80–saline. Animals received 3 mg β-carotene ip 18–24 hr before exposure to light.

Since publication of the report on these 3 patients in 1970, we have treated 130 additional patients with β-carotene in collaboration with their personal physicians (*10*, *11*). From our experience with this larger number of patients, we found that we often had to use higher doses of β-carotene beadlets (up to 180 mg/day) than we used with the first 3 patients; the dosage must be individualized for each patient (*10*, *11*). Of the 133 patients treated with these individualized dosages, 22 reported little or no improvement and the remaining 111 reported significant improvement in their ability to tolerate sunlight without developing symptoms of photosensitivity (table 3). Over 75% of the patients report a fourfold or more increase in tolerance to sunlight. The majority now engage in outdoor activities from which they excluded themselves before β-carotene treatment started. Most of the children can now play outside in daylight. Some patients still get reactions when they expose themselves for a long time to the sun. Others can spend all day outdoors with no trouble, and some only an hour or two before developing symptoms. In general, the treated patients report that they can tolerate sunlight better now than before treatment.

In addition to the patients' subjective reactions of improved tolerance to sunlight, we used phototesting with

TABLE 3.—*Effect of β-carotene on tolerance to sunlight of patients with erythropoietic protoporphyria*[a]

No. of patients	Percent of total	Protection index[b]
10	16	1[c]
12		2[c]
27	84	3–5
39		6–10
15		11–15
6		16–20
24		>21
Total 133	100	

[a] Data taken from (*10, 11*).

[b] Protection index is defined as the number of minutes of summer sunlight tolerated with the development of symptoms after therapy divided by the number of minutes of summer sunlight tolerated without the development of symptoms before therapy. An index of less than 3 represents no improvement.

[c] Patients showed little or no improvement despite blood carotene levels of at least 400 μg/dl following intake of highest dose appropriate for their ages.

xenon arc light before and during β-carotene therapy as an objective method of evaluating the effect of this treatment (*10, 12*). Tolerance to this light increased in those patients who reported benefit from carotene therapy. No increased tolerance was found in those patients reporting no improvement (table 4).

In the 6-year period of the study (1969–75), no toxic side effects (other than occasional transient loose stools) from the ingestion of these high doses of β-carotene (the equivalent of up to 4 pounds of carrots a day) were found. The carotenodermia which usually develops has not bothered most of the patients. Although we found in another study that β-carotene had no effect in preventing sunburn (*13*), it appears to have a small effect in increasing tanning as opposed to burning. Many of our patients reported that for the first time in their lives they were able to develop a tan.

Treatment with β-carotene has had no effect on the abnormalities of porphyrin metabolism that characterize EPP. All of the 133 patients had elevated erythrocyte, plasma, and stool porphyrins when they entered the study, and their porphyrins have remained elevated in spite of β-carotene treatment.

In 22 reports of the successful use of β-carotene for the treatment of photosensitivity in EPP, over 75% of the patients treated reported a significant improvement in their ability to tolerate light exposure, and no side effects from the use of β-carotene were observed (*14–35*). One study reporting little or no improvement has also appeared (*36*); however, these workers used a much lower dosage of β-carotene than that recommended by us (*10, 11*). Later, some of the patients from the unsuccessfully treated group were given higher doses of β-carotene by another investigator (*35*), and the patients noted some increased tolerance to sun while taking the higher doses. These results emphasize the importance, as we have mentioned (*10, 11*), of individualizing the dose to each patient and increasing the dose until the patient reports some improvement.

The problem of individualizing treatment is also important in the conduct of a controlled trial and makes double-blind designs almost impossible. At a minimum, such trials should use a dose of β-carotene large enough to produce amelioration of symptoms in most patients (a minimum period of 3 months' treatment at doses giving blood levels ≥800 μg/dl; for adults at least 180 mg/day should be given).

From our results and those of other workers it can be concluded that β-carotene administered in sufficiently high doses can be an effective therapy for ameliorating photosensitivity in most patients with EPP. However, it must be pointed out that there are limits to the protective ability of carotenoids. As can be seen from our data, some patients receive little or no benefit from carotene treatment. In general, these are patients who have very high levels of red cell and/or plasma porphyrins. Carotenoid administration seems also to offer a slight degree of protection in patients given iv hematoporphyrin for cancer investigation, but this protection is not sufficient to allow unrestricted activity (*2*). Thus it is important to realize that even when carotene doses are increased to the highest achievable levels, significant protection may not occur in the presence of extremely high levels of porphyrins.

Since β-carotene administration seemed effective in protecting against photosensitization in EPP, it seemed logical to see if it could prevent photosensitization in other photosensitivity diseases. There have been seven reports (*26, 37–42*) on the use of carotenoids in the treatment of congenital porphyria (Günther's disease). Five report some decrease in the number of new lesions produced, in some cases the patient is allowed fairly normal exposure to light. Seip et al.

TABLE 4.—*Tolerance to xenon arc light*[a]

Patient	Development time for minimal erythema, min	
	Before therapy[b]	During therapy[c]
1	13.33	36.67
2	20.00	40.00

39	2.00	10.00
42	5.00	15.00

[a] Data taken from (*12*). $P<0.001$ from paired *t*-test on data in table.

[b] Average for each patient of all phototests before therapy started, when patient first entered study, as well as tests done before therapy started in subsequent years of the study, when patient had not taken β-carotene during winter (serum carotene level <250 μg/dl) in all years patient was in study.

[c] Average for each patient of all phototests in which blood β-carotene level exceeded 400 μg/dl in all years patient was in study.

(*37*) report phototesting 1 patient with the use of a xenon arc light. Before treatment the patient reacted with marked erythema after 10 minutes' exposure to this light, and during treatment he developed only mild erythema after 40 minutes of exposure. These authors stressed, as we do, the importance of maintaining high levels of carotene in the blood. Here, as in EPP, carotenoids do not correct the biochemical defect, so it is important that whatever hematologic treatment the patient is receiving must be continued during carotenoid therapy. Carotene treatment will not heal old scars—hence the best cosmetic effects will occur if therapy is started when patients are very young.

Several groups of workers have reported the use of carotenoids (usually a mixture of β-carotene and canthaxanthin) in the treatment of PMLE with varying degrees of success (*33, 43–47*). Jansen (*43*) treated 66 patients, 51 of whom responded favorably. Wennersten and Swanbeck (*44*) treated 8 patients, all of whom showed improvements in the minimal erythema dose tested with an appropriately filtered xenon arc lamp. Thune (*45*) treated 17 patients, only 5 of whom showed a more than threefold increase in tolerance to sunlight. On phototesting, he found "a significant increase in MED [the minimum erythema dose] for unfiltered light (xenon arc) at the 5% level of probability." Some of the patients also needed a sunscreen to achieve maximal therapeutic effect. Haeger-Aronsen et al. (*33*) found improvement in 15 of 18 patients with PMLE. Parrish et al. (*46*) found complete remission in only 6 of 19 patients and got much better results using psoralen plus UV radiation treatment. In our collaborative study (*11*), only 9 out of 27 patients reported improvement with carotene treatment with most also needing the concurrent application of a sunscreen, though sunscreen alone was not beneficial.

Fusaro and Johnson (*47*) reported success in treating the hereditary form of PMLE found in American Indians with high doses of β-carotene. They treated 5 patients and stated that each patient was able to perform normal activities outdoors without avoiding the sun and without showing symptoms of photosensitivity and reappearance of skin lesions.

Although some workers have shown objective evidence by phototest of improved light tolerance in PMLE with carotene treatment, it is obvious from these various reports that carotenoids are not as effective in the treatment of PMLE as they are in the treatment of EPP. It would seem sensible to use carotenoids in the therapy of PMLE only when the usual modes of therapy are ineffective, impractical, or contraindicated.

Carotenoids have been found by other workers as well as by our group to be ineffective in the treatment of actinic reticuloid (*11, 48*), porphyria cutanea tarda (*11, 49, 50*), solar urticaria (*11, 26, 48*), and hydroa aestivale (*11*). Two groups of workers (*33, 51*) have found a beneficial effect of carotenoid treatment in lupus erythematosus, but another group had success in only 1 of 26 patients (*52*). Bickers et al. (*53*) suggest that β-carotene may be effective in ameliorating the photosensitivity in hydroa vaccineforme, and Husquinet et al. (*54*) have reported some success in a patient with porphyria variegata who developed no lesions for 2 years while taking β-carotene, in spite of elevated stool and urine porphyrins. Eales (*30*) reported also some success in treating this disease. Pietzcker (*55*) reports successfully using carotenoids to ameliorate the appearance of certain patients with vitilligo.

Since few patients with these various diseases have been treated with carotenoids, we still do not know the extent of the pigment's effectiveness in these conditions; clearly more work needs to be done. However, since the above-described studies have also reported no significant toxicity from carotenoid ingestion, it is probably sensible to give a trial of β-carotene (or β-carotene and canthaxanthin, as is used in Europe) to patients with any kind of photosensitivity disease, who have not responded to other forms of therapy. In EPP, carotenoids seem to be the treatment of choice.

How carotenoids might be exercising their protective function is being actively investigated at this time. Studies to date suggest that the high levels of protoporphyrin present in the erythocytes, plasma, or extracellular fluid of the skin can be stimulated to an excited (triplet) state by visible light, which can penetrate skin to the level of the dermal capillaries (*56*). The excited protoporphyrin may either destroy cell components directly or may react with molecular oxygen to form singlet oxygen, a moiety that can be highly damaging to cellular components. Direct cell damage, or damage to cells or cellular organelles such as lysosomes, with release of chemical mediators that in turn damage other cells or organelles, would then cause the manifestations of itching, burning, erythema, and edema experienced by the patient with EPP.

β-carotene can quench singlet oxygen and inhibit free radical formation in vitro (*57, 58*) as you have heard in Dr. Krinsky's presentation at this meeting (*59*), and the ability of bacterial carotenoids to confer protection is correlated with the ability of the carotenoids to quench singlet oxygen in vitro (*60*). However, some degree of free radical inhibition by carotenoids is a possible alternative mechanism of action. Mechanisms of carotenoid protection in EPP have not yet been studied in an animal model. Further work should elucidate the definitive mode of action of the carotenoids' protective effect in animal models and eventually in patients with EPP.

In nonporphyric photosensitivity diseases, the chromophore responsible for the abnormal reactions is not known and is in all likelihood different from that in EPP: The mechanisms responsible for the induction of abnormal responses may not have the same molecular basis. Thus it is not surprising to see that for some diseases carotenoids may not be as an effective a photoprotector as they are in EPP. Here also, much work must be done on the mechanisms of photosensitization in these diseases.

The results of studies done by us and other workers show that carotenoid therapy—when given in high enough dose—is usually effective in ameliorating the photosensitivity in EPP, and it may be of some value in certain patients with other forms of photosensitivity.

DISCUSSION

P. Sundaresan: I was wondering about the variation you were getting with the different patients. Was the carotene administered orally in these patients?

M. Mathews-Roth: Yes, β-carotene was administered orally. Humans are "yellow fat" animals, and if we take β-carotene by mouth, we accumulate high levels in the skin and in the blood. Yes, it is true there is physiologic variation from people to people as to blood levels. Also, in some of our patients, compliance might not have been as good. We really could not totally push them to take six pills a day all the time. Some people just refused to take six pills a day, and we just took their blood, determined the β-carotene level, and took their word for their reaction. Some of that variation is probably due to the fact that some of the people were not taking enough pills to attain drug levels as high as they should have been.

Sundaresan: Probably the variation is also due to poor absorption of carotene. Because carotene is very poorly absorbed, as you know, I was wondering if there is any way of improving the patients' absorption. You might then be able to give the carotene at a lower dose.

Mathews-Roth: It is very true that crystalline β-carotene is extremely hard to absorb. What we have been using are the Hoffman-LaRoche β-carotene beadlets, which the FDA had approved for use as a food color. This is a water-miscible beadlet, and I think it is about the best way to get carotenoids into anyone. We did a well-controlled study on carotene intake in the sunburn study that I referred to (*13*). This was done with Dr. Fitzpatrick's collaborative investigators at the Arizona State Prison, and the men in the study were taking their pills judiciously. They indeed developed high levels fairly soon, in 4-6 weeks. That time is fairly standard for that dose of carotene. When they took their pills, these people did develop the kinds of levels that theoretically we thought they should.

I think that the β-carotene preparation we have is probably about the best we can get, and unless Hoffman La-Roche comes out with a better water-miscible formulation, I think we are doing pretty well with the one we have.

If I can also add my request to the FDA for what drugs they should investigate, it would be that hematoporphyrin derivative. For one thing, it concerns me that investigators are giving this material that they are preparing in their own labs intravenously to patients and that these patients remain photosensitive for weeks. If this therapy ever does get a bit more use, and admittedly people are trying to use it topically, the FDA should be attempting to monitor its use.

Another thing that you might be interested in (and I think the FDA is aware of it) is that people are marketing in Europe canthaxanthin as the European answer to Man-Tan. Instead of having to smear something on you to look tanned and attractive, you can take a pill. Indeed, the patients in Europe who are taking, for porphyria, the mixture of β-carotene and canthaxanthin do like the cosmetic appearance much better than our patients in the United States who are just taking the β-carotene.

So far, no toxicity has occurred. However, we do not know as much about canthaxanthin as we do about β-carotene. It would seem to me that the oral use of canthaxanthin should be classified as a drug, be it for a cosmetic purpose or not, because of the fact that its users are taking it by mouth and they are taking it in the same range of dose that people with porphyria are taking it. It would seem to me that some studies comparable to those that we did to get the new drug approval for β-carotene (Solatene) should be done by these people who want to market canthaxanthin for a tanning effect. It works: There is no doubt about the efficacy. People who take it look great. In fact, I do not know if Dr. M. Pathak remembers, but when we first started out and did a β-carotene UV study, some of our residents wanted to stay on it (β-carotene) because they looked so good.

N. Krinsky: I wonder if you could just comment on the level of vitamin A in the serum of the people on the high β-carotene regimen, and also if you have any idea what happens to vitamin A storage in the liver?

Mathews-Roth: One of the things that you always read in pharmacology books is that if you administer vitamin A as a β-carotene, you do not get high levels of vitamin A. The body shuts off the vitamin A converting mechanism, and indeed we found this to be true. Our patients never exceeded the normal range of blood vitamin A. Now, this vitamin A determination was admittedly not done by liquid chromatographic methods but done by the standard clinical lab test for vitamin A. This has been reported routinely in the literature from old studies done from β-carotene administration. It has been confirmed as far as I can tell in all of the studies on protoporphyria. None of these studies reported high levels of vitamin A, and it was confirmed also in our prisoner study. The subjects' vitamin A levels stayed within the normal range.

We had the opportunity to look at livers of 2 patients who were receiving β-carotene, one of whom was a protoporphyria patient who had a gallbladder attack. Her gallbladder was removed, and her surgeon provided us with a small amount of her liver. The other one was a child with a genetic disease who was being given β-carotene at the request of her father to improve the skin appearance. She died of a totally unrelated cause. We were able to get some liver from her, and both of these livers did contain a normal level of vitamin A. There are several reports in the literature of people who were caratonemic and also had normal liver vitamin A levels. Also, liver β-carotene was not particularly increased. I think this was also shown by Hoffman LaRoche years back in some animal studies that they had done, and again, the administration of carotene does not lead to abnormally high stores in the liver of either carotene or vitamin A, which is why it is such a great compound to use for this kind of work.

M. Pathak: The textbook of biochemistry that you and I studied had to be changed because the enzyme system just does not convert under in vivo conditions one molecule of β-carotene to two molecules of vitamin A. I think there are a couple of good papers published from the Massachusetts Institute of Technology showing that the enzyme actually gets inhibited by high levels of vitamin A.

Mathews-Roth: Right, and thereby keeping the vitamin A levels at normal ranges. Yes, anyway, theoretically, β-carotene should cleave to two molecules, and I think in vitro it does it, but in vivo it does not. So β-carotene is a nice safe preparation to use.

Ocular Phototoxicity and Psoralen Plus Ultraviolet Radiation (320–400 nm) Therapy: An Experimental and Clinical Evaluation[1,2,3]

Sidney Lerman, *M.D.*[4,5]

ABSTRACT—The increase in fluorescent chromophores within the human ocular lens is age related, leading to an increasingly yellow core (nucleus) that presumably results from UV radiation exposure. In approximately 10% of our population this process progresses more rapidly, resulting in the formation of the brown (nuclear) cataract. Some lenticular discoloration may be beneficial, since it enables the mature lens to filter UV and short-wavelength visible radiation, thus protecting the retina from potential photodamage. Aphakic primate retinas can be irreversibly damaged by exposure to approximately 5 $\mathrm{mW \cdot cm^{-2}}$ long-wavelength UV (>325 nm) radiation. Photosensitized damage to the lens and retina with psoralen plus UV radiation (320–400 mm) (PUVA) has been demonstrated in experimental animals, and cataracts have recently been reported in patients given PUVA therapy. A new method to screen patients for lens damage is by enhanced fluorescence measurements. This method, UV slit-lamp densitography, permits detection of lenticular photodamage at a molecular level, years before visible opacities become manifest by conventional slit-lamp examination. This procedure has also demonstrated a significantly lower level of lens fluorescence (hence decreased filtering capacity) in patients with retinal degenerative diseases, suggesting UV photodamage as a factor in the progression and perhaps pathogenesis of these conditions.—JNCI 1982; 69:287–302.

Aside from the skin, the eye is the only organ or tissue in the body that is particularly sensitive to the nonionizing wavelengths of radiation normally present in our environment (wavelengths >280 nm). We are constantly exposed to UV radiation (solar and man-made) throughout life; approximately 8% (110 $\mathrm{W \cdot m^{-2}}$) of solar radiation above the atmosphere is estimated to be UV. At sea level the amount of UV radiation declines to 20–50 $\mathrm{W \cdot m^{-2}}$, depending on geographic location and season. Aside from solar radiation, man-made UV radiation may also play a role in ocular phototoxicity, albeit a relatively minor one under normal circumstances. The spectral output of commonly used fluorescent lamps is relatively low at these wavelengths and should not pose a problem except in special circumstances, e.g., in patients who are being treated with photosensitizing drugs. However, exposure to photoflood lamps or the black light lamps frequently used in various laboratories might present a potential hazard because their output can approach approximately 5–10% of the average levels of solar radiation in our atmosphere. Furthermore, a much more significant hazard exists in certain industries that utilize UV radiation in catalytic polymerization processes.

UV radiation-induced changes in human and animal ocular tissues can be attributed to two mechanisms: a direct or intrinsic process in which the radiation is absorbed by specific naturally occurring chromophores within these tissues (e.g., the nucleic acids or aromatic amino acid residues) and an indirect or photosensitized process in which the radiation is initially absorbed by a photosensitizing drug or other extraneous compound (text-fig. 1).

DIRECT UV RADIATION EFFECTS

Corneal photodamage from UV radiation has been appreciated and recorded for a long time, a typical example being snow blindness experienced by polar explorers. This type of photokeratitis is due to the relatively high levels of UV radiation that can be reflected by snow compared with less than 5% of UV radiation that is reflected from earth or grass. Aside from the well-known polar and industrial photokeratitis, UV radiation has also been implicated in a variety of conjunctival and corneal lesions. These lesions include pingueculae and pterygiums, exposure keratosis (which involves epithelial changes related to actinic radiation and is analogous to actinic keratosis of the skin), nodular band-shaped keratopathy, experimentally induced tumors in animals, and the relatively rare dysplasia and intraepithelial carcinoma. Certain corneal diseases can also be triggered by exposure to UV radiation, e.g., herpes simplex keratitis and recurrent erosions of the cornea. Experimental UV photokeratitis is generally associated with an action spectrum in which the major peak is at 280 nm and the minor one is approximately 260 nm (*1*, *2*).

The normal human cornea and aqueous humor transmit nearly all UV radiation longer than 300 nm; however, there is a small but progressive decline in the percent of UV radiation transmitted as the cornea ages, which may be due to an accumulation of UV radiation-induced fluorescent chromophores in the aging cornea (*2*). Thus the human ocular lens is constantly exposed to ambient UV radiation (300–400 nm) throughout life. One consequence of cumulative photochemical damage is an increasing absorption of UV radiation and visible light due to the presence of

TEXT-FIGURE 1.—UV radiation effects on the ocular lens with particular emphasis on lens protein photoreaction.

intrinsic and photochemically generated lens chromophores (*1–20*).

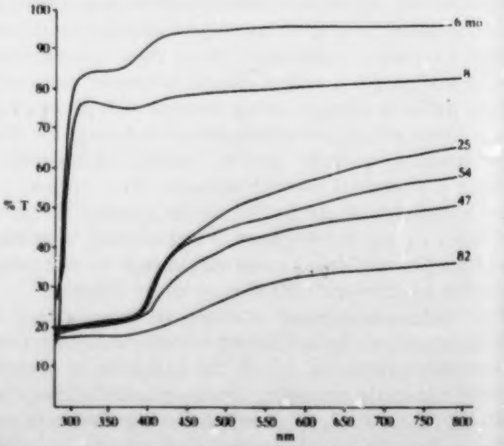
We have demonstrated that UV radiation can markedly affect the intact lens by direct absorption, both in vivo and in vitro. In vitro UV radiation-induced changes in human lenses include increased fluorescence intensities at 440 and 520 nm and increased pigmentation (*13–16*). Similar fluorescence enhancement can be observed in UV-irradiated rat lenses both in vitro and in vivo (*16*). Our studies indicate that these photochemical changes are similar to the increasing fluorescence seen in normally aging human lenses (*13*, *15*). The cumulative effects of chronic exposure to ambient UV radiation appear to include the generation of a series of fluorescent chromophores (absorbing at increasingly longer wavelengths), an increasingly yellow lens nucleus, and a progressive increase in the level of insoluble lens proteins. The increase in the level of insoluble lens protein may also be related to the cross-linking of previously soluble polypeptides by some of the fluorescent pigments (*6*, *9*, *11*, *15*) as well as to the formation of disulfide bonds (*15*, *20*, *21*).

Our UV radiation and visible light transmission studies on normal human lenses ranging in age from 6 months to 82 years have shown that more than 75% of the UV radiation (300–400 nm) is transmitted by lenses less than 10 years of age, whereas transmission of the same radiation by lenses more than 25 years of age drops markedly to 20% or less (*13*, *15*, *20*) (text-fig. 2). These data are consistent with the relative lack of UV radiation-absorbing chromophores in the young lens and the increasing concentration of such chromophores as the lens ages. Accompanying the measured increase in these chromophores and decrease in light transmission is an increase in the yellowness of the lens nucleus as it ages (fig. 1). These pigments are mainly confined to the nucleus and may be a factor in the development of nuclear sclerosis. The extreme example of such an aging process is the brown or black nuclear cataract (fig. 1J).

PAS performed on normal aging lenses and brown nuclear cataracts reveals an absorption band at 340–360 nm which increases in intensity as the lens ages and is particularly pronounced in brown cataracts (*22*). The intensity of this PAS-absorbing region is directly correlated with the degree of coloration of the lens nucleus. These data provide further evidence that UV radiation-absorbing pigments accumulate in the aging lens and brown nuclear cataract and are associated with the changes in light transmission and fluorescence in such lenses.

In comparing the action spectrum for production of fluorescent material in lenses (*23*) with that for photochemical destruction of Trp in aqueous solution (*24*), we suggested that Trp residues in lens proteins could be the initial light-absorbing and photochemically active species in UV radiation-induced lens damage. ESR studies point to an initial free radical mechanism for this photochemical lens damage (*25*). Further evidence regarding this mechanism derives from our studies with D-penicillamine. This free radical scavenger greatly reduces the free radical signal in UV-irradiated lenses and prevents the photochemical generation of fluorescent chromophores (*15*, *25*). Lens tissue has built-in mechanisms for combating free radical damage. One of these mechanisms utilizes glutathione (which is present in very high concentration, particularly in the cortex) as a free radical scavenger. If this protective mechanism were suppressed, the damage due to UV radiation exposure would be significantly increased.

Our in vitro studies with whole lens incubates (mouse, rat, and human) have demonstrated that the production of fluorescent chromophores can be markedly accelerated if the lenses were incubated in the presence of 3-AT during UV irradiation (*16*). Because 3-AT is a catalase inhibitor, more glutathione is consumed in such lenses, resulting in the depletion of this important lens free radical scavenger and thereby increasing the sensitivity of the lenses to UV radiation. The high concentration of glutathione in the cortex



TEXT-FIGURE 2.—Percent transmission (% T) of UV radiation and visible light of normal human lenses 6 mo to 82 yr of age.

would prevent (or abort) a free radical-induced photochemical generation of these fluorescent chromophores while the lens nucleus, which has a much lower level of glutathione, does not have such an effective protective mechanism and would, therefore, accumulate these photochemically generated pigments (*13*, *15*, *16*). This enables the cortex to remain clear while the aging nucleus becomes progressively more yellow to brown. In addition to UV radiation-induced free radicals, singlet oxygen is also involved in direct UV radiation photodamage as well as in the photodynamic action of 8-MOP on lens proteins (*26*, *27*).

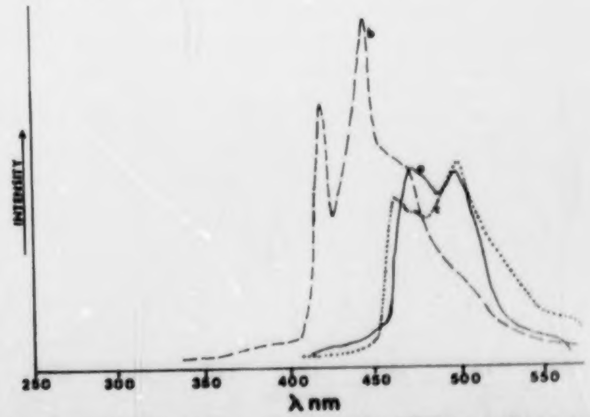
Thus it is now generally accepted that chronic exposure to UV radiation (300–400 nm) over an individual's lifetime leads to the generation and increased accumulation of various fluorescent chromophores in the lens; these fluorescent chromophores are, to some extent, responsible for the increased yellowing of the lens nucleus as it ages. [In about 10% of our population this process progresses more rapidly, resulting in the development of the brown (nuclear) cataract.] This type of discoloration, in moderation, is actually beneficial because it enables our lens to become a very effective filter for UV and short-wavelength visible radiation (by our second to third decade), thus protecting our retina from cumulative photochemical damage which could occur during our lifetime. Laboratory studies have shown that such radiation can cause irreversible retinal photodamage (*28*). Interestingly, nature has provided us with the ability to develop a lenticular UV radiation filter to protect our retina from continuous radiation exposure which could be harmful, particularly in the older individual whose retinal metabolism and repair processes are no longer as effective as they are in the younger individual. We are now beginning to see confirmation of our hypothesis that long-wavelength UV radiation may play a role in certain retinal diseases (e.g., cystoid macular edema) which tend to occur in older patients after their cataractous lenses are removed.

Aside from the effects of chronic exposure to ambient UV radiation, acute exposure to higher radiation levels can produce cortical opacities in human, rat, and rabbit lenses in vitro and in vivo (*29–32*). Thus more intense UV radiation (≥300 nm) can induce lens changes involving the cortex, whereas chronic exposure mainly affects the lens nucleus. These effects appear to be dose and time related (*31*, *32*). Our UV radiation exposure experiments have demonstrated that cortical opacities can be induced in young rat lenses (in vitro) by exposure doses (at 300 nm) greater than 26 J, concentrated within a relatively short time period (*32*). We have previously demonstrated that rat lenses will develop an increasing level of 440-nm fluorescence and become yellow at irradiance levels of 0.4 $\text{mW}\cdot\text{cm}^{-2}$ within 6 hours (*16*). However, when the irradiance is increased by a factor of four or more, cortical opacities develop within 4–6 hours, and these anterior cortical opacities appear to prevent any marked increase in lens fluorescence (*32*). It is postulated that this more intense UV radiation is capable of inducing severe photochemical damage to important enzyme systems (e.g., catalase and glutathione dehydrogenase). Chronic exposure of these enzymes to lower levels of irradiance could be overcome by the lenticular reparative mechanism enabling the photochemically induced fluorescence changes within the structural lens proteins (e.g., 440- and 520-nm fluorescence) to proceed and become manifest. There is also the possibility that more intense UV radiation may affect the protein–water order within the lens, resulting in the formation of "water lakes" associated with protein aggregates. The formation of water lakes would give rise to localized areas of marked changes in refractive index in the injured site and result in light scattering and opacification. Recent studies on rabbit lenses exposed to 337 nm of laser radiation demonstrate marked changes in their water component (*33*). These wavelengths have sufficient photon energies (~1–1.5 eV) to disrupt the protein–water order in the lens and give rise to sudden changes in refractive index resulting in localized opacities.

PHOTOSENSITIZED UV RADIATION EFFECTS

In addition to the demonstrated direct photochemical action of UV radiation on the ocular lens, photobiologic damage is possible by means of photosensitized reactions due to the accumulation of certain drugs within this organ. After the 13-mm stage of development, the ocular lens is completely encapsulated and never sheds its cells throughout life. Therefore, after 8-MOP therapy, photobound 8-MOP could be retained and accumulate with repeated therapy. We have demonstrated the presence of 8-MOP in human lenses 12 hours after the patient had ingested a single therapeutic dose of this drug (*26*, *34*) (text-fig. 3). "Free" 8-MOP can also be detected within 2 hours in rat and dogfish lenses after one ip injection, and we have shown that it diffuses out of these lenses within 24 hours if the animals are kept in the dark (*35–37*).

In the presence of photic stimuli [ambient room light as well as direct UV (320–380 nm) radiation], lenticular fluorescence and phosphorescence are enhanced (*36*). Our spectroscopic studies have shown that photoaddition products (at 360 nm exposure) can be generated with lens proteins as well as with Trp (in vitro) in the presence of 8-MOP and oxygen (*26*, *38*). Such a reaction in vivo would result in the

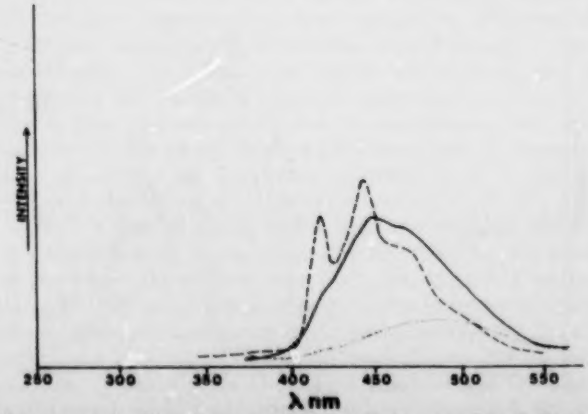


TEXT-FIGURE 3.—Phosphorescence spectra (at 77°K) at various wavelengths (λ) of a 27-yr-old lens (derived from an enucleated eye 12 hr after the patient was given 0.75 mg 8-MOP/kg). a) 8-MOP phosphorescence (——) in lens (equivalent to 10^{-7}-*M* concentration); b) Trp phosphorescence (-----); c) 8-MOP solution in ethylene glycol (·····).

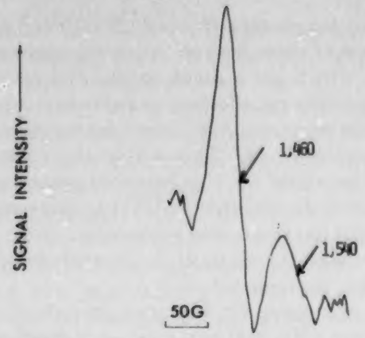
permanent retention of the photoproduct within the ocular lens. One such photoproduct has recently been demonstrated in lenses derived from rats given 8-MOP (1 mg ip) and exposed to UVA (320–390 nm) radiation (*39*) (text-figs. 4, 5).

The photosensitizing action of the psoralen compounds has been correlated with the generation of cyclobutane photoaddition products with thymine in DNA molecules (*40*). A similar mechanism has been proposed for 8-MOP-photosensitized lens damage (*41*). The effect of such binding would be an enhanced potentiation of the photosensitizing action of the psoralens; i.e., the 4′,5′-cyclobutane photoadduct between 8-MOP and thymine could act as a new photosensitizer (absorbing at 365 nm), resulting in the formation of interchain cross-links in DNA (*42*). 8-MOP may also exert a photodynamic action involving singlet oxygen in the lens and forming photoproducts with aromatic amino acids, particularly Trp residues. Nuclear magnetic resonance analyses of the photoreaction between 8-MOP and Trp demonstrate the loss of hydrogen at the 3,4,4′ and 5′ positions of 8-MOP and at the indole C_2 position of Trp, with concomitant changes in the aliphatic regions of the spectra (*38*). Since the positions involved in this reaction are the same as those reported in cyclobutane photoadduct formation with thymine, the reaction between 8-MOP and Trp could involve a cyclobutane type of photoproduct.

We have also demonstrated that 8-MOP is capable of entering the corneal epithelium, the ciliary processes, the ocular lens, and the retina (of young rat and dogfish eyes) within 2 hours after a single ip dose of 1 mg labeled 8-MOP (*43*). When the animals are maintained in the dark, no 8-MOP can be demonstrated by spectroscopic methods, by autoradiography, or by scintillation counts after 24 hours. However, when the animals are exposed to relatively low levels of 365 nm of UV radiation, a photoreaction (or photoreactions) occurs which results in the binding of 8-MOP within these tissues (text-fig. 6; figs. 2, 3). In the cornea, bound 8-MOP accumulates mainly in the epithelium, but because of its excellent reparative mechanisms, the bound 8-MOP disappears within 3 or 4 days in spite of continuous UV radiation exposure. Therefore, 8-MOP therapy should not prove to be a significant hazard to the cornea. However, since the 8-MOP in the retina is capable of being stimulated by 365 nm of radiation (the lenses in these young animals are not effective filters for this wavelength), 8-MOP photoproducts quickly develop in the inner nuclear layer. It would thus appear that photobound 8-MOP can accumulate in the retina as well as the ocular lens in animals whose lens is not an effective UVA radiation filter. Repeated injections of 8-MOP to such animals could result in an increasing accumulation of photoproducts in these two ocular tissues. Such photoproducts could then act as new photosensitizing agents within these tissues, thereby enhancing photochemical damage caused by UV radiation. The preceding data demonstrate that 8-MOP therapy could pose a potential hazard not only to the ocular lens but also to the retina in young people whose lenses are not effective UV radiation absorbers and/or in aphakic and pseudophakic individuals, particularly if they are exposed to repeated PUVA therapy.

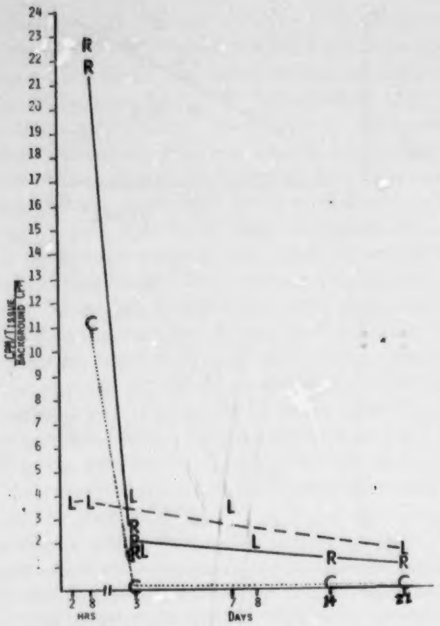


TEXT-FIGURE 4.—Phosphorescence spectra at various wavelengths (λ) of a rat lens treated with 8-MOP and UVA radiation. New phosphorescence (325-nm excitation) is now apparent (——) as well as is a relatively structureless 360-nm excitation phosphorescence (·····) which represents intrinsic chromophore phosphorescence in such lenses. Trp phosphorescence (-----) is also shown.



TEXT-FIGURE 5.—ESR spectra of same lens as shown in text-fig. 4. Aside from the Trp triplet [at 1,460 gauss (G)], a new triplet at 1,540 G is now present (ν = 9.10 GHz). These two triplets correspond to the triplets noted by phosphorescence spectroscopy for Trp (290-nm excitation) and the new 325-nm excited photoproduct as shown in text-fig. 4. Their respective lifetimes are 6.8 sec (Trp) and 2.4 sec for the photoproduct.

Because laboratory studies have demonstrated enhanced fluorescence in the ocular lens to be associated with aging and PUVA therapy and because presumptive PUVA cataracts have recently been reported (*44*), we have developed a method to monitor lens fluorescence in vivo (*45*). A new slit-lamp densitographic apparatus constructed on the Scheimpflug principle, capable of accurately and reproducibly recording visible changes in lens density as the lens ages, was recently introduced (*46–48*). We have modified this apparatus to utilize UV radiation at wavelengths of 300–400 nm, to excite the UV radiation-absorbing chromophores in the lens, and to reproducibly photograph the ensuing fluorescence. Because the regions of lens fluorescence (440 and 520 nm) require wavelengths of 340–360 nm and 400–420 nm, respectively, for excitation, we can utilize UV radiation to measure and quantitate the age-related fluorescence levels in the normal lens in vivo and correlate them with our in vitro data reported in previous communications (*13–15*) (text-fig. 7). We can also detect abnormal fluores-

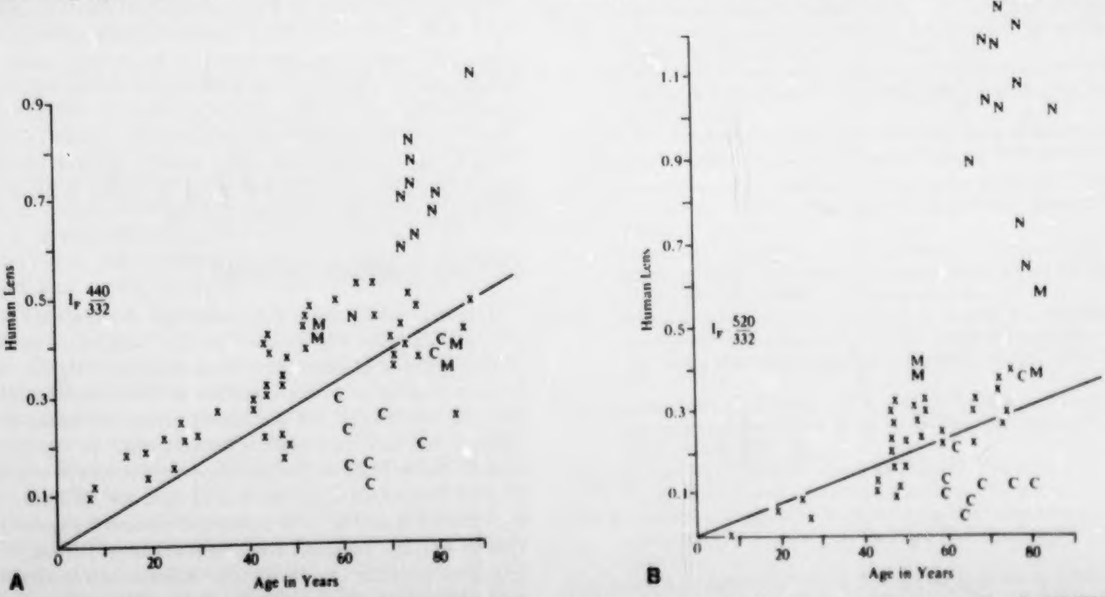


TEXT-FIGURE 6.—Total radioactivity expressed as a ratio of cpm per tissue divided by background cpm in retina (R) (——), cornea (C) (·····), and lens (L) (-----) derived from rat and dogfish eyes following one injection of ^{3}H- or ^{13}C-labeled 8-MOP and exposed to UVA radiation for varying times. This ratio was used because the experiments were performed in two different scintillation counters (Marine Biological Laboratory and Emory University).

cence levels or emission wavelengths in patients exposed to levels of UV radiation that exceed ambient levels and/or to photosensitizing agents.

UV SLIT-LAMP DENSITOGRAPHY

We have modified a Topcon (Topcon USA) visible radiation slit-lamp densitography apparatus to obtain in vivo lens fluorescence data. Specially coated quartz filters (which transmit only UV radiation ~290–410 nm) are placed in front of the 200-W xenon lamp light source. Since the regions of lens fluorescence that we are currently evaluating require wavelengths of 340–360 and 400–420 nm for excitation, these filters permit us to utilize UV and short-wavelength visible radiation to measure and quantitate the age-related fluorescence levels in the normal lens in vivo and to correlate these data with the in vitro data previously reported. We have refined our present in vivo studies by adding new filters so that we can obtain fluorescence measurements in vivo at 20-nm bandwidths (e.g., 340–360, etc.). The 200-W xenon light source in the camera has sufficient spectral output in the 320- to 420-nm region so that we are able to utilize these filters and obtain levels of irradiance at the lens (in vivo) sufficient to excite its chromophores and obtain reproducible fluorescence data which can be analyzed by microdensitography. We used the conventional slit lamp to examine all patients with mydriasis (7- to 8-mm pupillary diameter) and then photographed them with our apparatus first with visible radiation and then with UV radiation. The camera position for all photographs is at 0° and 180°. The resulting negative strips are analyzed by microdensitography, and the data are plotted as densitograms. Three specific regions can be selected from the UV radiation densitograms, and two of these have been correlated with the 440- and 520-nm emission peaks obtained from our in vitro studies with fluorescence spectroscopy on whole normal lenses. We are thus able to obtain fluorescence emission data which can be attributed to and quantified for

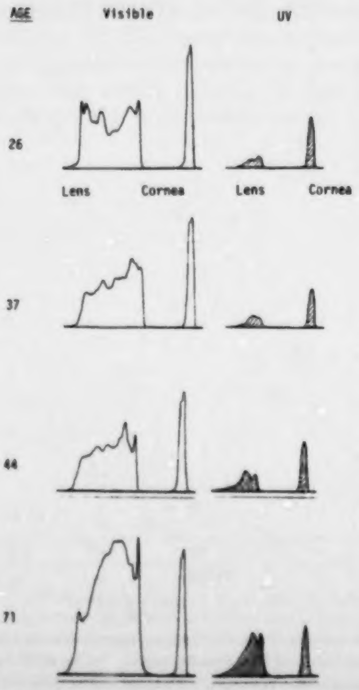


TEXT-FIGURE 7.—Increase in A) 440-nm and B) 520-nm fluorescence emission levels in the normal aging human lens (x) expressed as I_F 440/332 and I_F 520/332, respectively. Each ratio represents the measured fluorescence intensity divided by the intrinsic Trp fluorescence emission at 332 nm in the lens. Similar measurements show marked elevations of the 440- and 520-nm fluorescence levels in nuclear cataracts (N), slight elevations in mixed nuclear plus cortical cataracts (M), and below normal levels in anterior cortical cataracts (C).

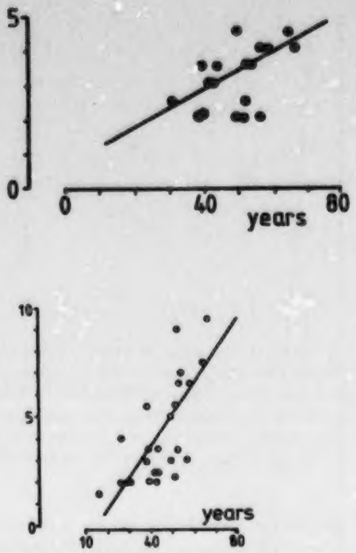
specific emission peaks so that in vivo data can be compared with in vitro whole-lens fluorescence spectroscopy.

Representative in vivo UV and visible radiation slit-lamp photographs obtained from normal individuals at 26, 37, 44, and 71 years of age and corresponding densitograms from these photographs are shown in figure 4 and text-figure 8. Detailed analyses of such densitograms on a series of normal eyes ranging in age from 17 to 85 years demonstrate an age-related increase in three peaks. Two of these peaks were determined to correspond to the 440- and 520-nm fluorescence peaks derived from our in vitro whole-lens fluorescence spectroscopy data, and a close correlation can be observed (text-figs. 7, 9). We are currently attempting to define and correlate the third in vivo densitography region with more detailed analyses of the simulated in vivo UV radiation densitograms (on whole donor eyes) and subsequent fluorescence spectroscopy on the cornea and lens. Aside from the age-related increase in lens fluorescence determined by these in vivo studies, we have also noted a posterior shift of the fluorescent peaks with increasing age. Our data also demonstrate a small but significant increase in corneal fluorescence with age, which correlates with our previous in vitro observations (*2*, *20*). Thus UV radiation slit-lamp densitography should provide an objective and reproducible method for monitoring at least one parameter of lens aging.

Preliminary studies of patients accidently exposed to levels of UV radiation that exceed ambient levels and/or to photosensitizing agents such as the psoralens demonstate an enhancement of lenticular fluorescence (figs. 5, 6). This demonstration could provide us with a useful diagnostic and prognostic tool in such patients as well as provide a relatively simple screening procedure. Inasmuch as enhanced lens fluorescence appears to occur months to years before lens opacities become manifest by conventional slit-lamp examination, measures could be instituted which at least retard or prevent UV radiation-induced (direct or photosensitized) lens opacities. One simple approach (which we are now utilizing for patients on PUVA therapy) consists of advising those individuals who have abnormal fluorescence levels to wear UV radiation-absorbing or reflecting lenses. These lenses permit over 90% transmission of visible light and can therefore be worn with comfort indoors as well as outdoors. This is of particular importance for patients receiving PUVA therapy because even indoor fluorescent lighting contains sufficient UV radiation to cause 8-MOP photobinding within the lens (*20*, *32*, *34*).



TEXT-FIGURE 8.—Densitograms corresponding to eyes shown in fig. 3.



TEXT-FIGURE 9.—Increase in the two densitographic regions ● and ○ that correspond, respectively, to 440-nm (text-fig. 7A) and 520-nm (text-fig. 7B) fluorescence emission levels obtained in vitro. *Ordinate values* are arbitrary units.

FUTURE CONSIDERATIONS

The increasing use of phototherapy in medicine as well as the fact that we are located in the "sun belt" provides us with a unique opportunity to develop a program whereby we will be able to screen patients and determine which ones are risk candidates for the development of direct and photosensitized UV radiation photodamage to certain ocular tissues. Aside from detecting abnormal levels or wavelengths of lens fluorescence in the living eye, we can also test our hypothesis that the UV radiation-filtering capacity of the lens in certain patients with degenerative retinal disease is less than normal; i.e., the ocular lens in such individuals has not developed enough photochemically induced chromophores for it to absorb all the UV radiation. By the time 90% of the population reaches its fourth to fifth decade, the lens has become a very effective filter for UV and shortwave visible radiation (320–450 nm), thereby protecting the aging (and metabolically less efficient) retina from potential damage. These wavelengths can cause retinal photodamage as demonstrated by experiments in primate eyes (*28*), and we can now determine whether this occurs in the human. We have begun a program whereby we are examining all patients with retinal disease (referred by our retina service). These patients are evaluated by UV radiation slit-lamp densitography and also have their retinas independently evaluated by fundus photography and fluorescein angiography. Preliminary results demonstrate a significantly lower level of lens fluorescence in patients with degenerative retinal disease (compared with corresponding values for their age group), indicating that their lenses are less effective in filtering out the 320- to 450-nm wavelengths of radiation. A larger clinical study is required to prove that the inability to completely remove these wavelengths may play a significant role in the development and/or acceleration of certain forms of degenerative retinal disease in the older population. In view of the increasing use of plastic intraocular lenses, which transmit much more UV radiation than do glass lenses (i.e., they effectively transmit wavelengths shorter than 320 nm), questions have been raised regarding potential UV and shortwave visible (320–450 nm) radiation damage to such patients. For example, Dr. J. Tennant (personal communications) has indicated that protecting such patients with UV radiation-absorbing glasses significantly reduces the incidence of postoperative cystoid macular edema. Thus the demonstration that UV radiation can play a role in the pathogenesis of retinal degeneration in certain "phakic" individuals would indirectly corroborate the possible relationship between retinal disease and 320- to 450-nm radiation in phakic as well as aphakic individuals. We believe that our clinical UV radiation slit-lamp densitography study can provide hard data to answer this question.

In view of the confusion and controversial claims regarding the efficacy of commercially available sunglasses in protecting the eye from UV radiation photodamage, we have recently analyzed a large series of such lenses to determine their transmission characteristics. Their ability to transmit UV and visible radiation (280–750 nm) was measured in a recording spectrophotometer. Photon flux measurements were also performed (with a Hewlett-Packard calibrated flux meter) with the lenses exposed to a 200-W mercury light source filtered to transmit only 280- to 390-nm radiation. These studies (*49*) demonstrated a wide variation in the UV radiation transmission characteristics of the sunglasses evaluated, ranging from 1.5 to 40% with similar transmission values noted when the sunglasses were tested for more discrete wavelengths, i.e., 340–380 nm. Only the Spectra-Shield and UV 400 lenses were more than 99% effective in filtering the UV radiation. It should also be noted that visible radiation is significantly decreased in certain darkly tinted sunglasses, whereas these sunglasses still transmit some long-wavelength UV radiation. In patients with blue, gray, or hazel eyes who wear such sunglasses, a 50% or more decrease in visible radiation can result in pupillary enlargement of 0.25–0.5 mm, thereby increasing the UV radiation incident on the intraocular tissues.

DISCUSSION

D. Valenzeno: Given the fact that light above 400 nm can get through to the retina, what do we know about retinal sensitization by sensitizers that absorb in the visible range?

S. Lerman: Do you mean the porphyrins?

Valenzeno: Yes.

Lerman: I do not know of any reported problems. Actually, as I have noted, most of our lenses act as very good short-wavelength visible filters, as well as UV radiation filters; and we really do not need any of that radiation below 500 nm for central visual activity. Thus a good deal of that radiation is filtered out as well, protecting the retina from the photosensitizers, which are activated at or below those wavelengths.

T. Nigra: I would like to ask about the posterior subcapsular cataract that is induced by steroids versus the cataract you showed in that patient who you said had a PUVA-induced cataract, and did that patient by any chance have steroids?

Lerman: No, he did not, and actually that was not a posterior subcapsular cataract. As I tried to point out, to look at a lens and say what caused the cataract is, in my opinion, rather questionable because a lot of lens changes can look alike and be caused by a variety of different insults (drugs, radiation, endocrine, and metabolic problems). However, if a person is on long-term steroids and has posterior subcapsular changes which have a certain pattern, it is at present acceptable to classify the cataract as a steroid cataract, assuming you have ruled out other cataractogenic factors.

Concluding Remarks[1]

Constantine Zervos[2]

We have come to the end of this symposium on photochemical toxicity, and I would like to take a few minutes to thank a lot of people and to briefly summarize our accomplishments over the last 2 days.

Let me begin by thanking the speakers who provided us with excellent presentations describing the frontiers of the field of photochemical toxicity. I also thank the symposium participants, the audience, who have also been excellent. Mrs. Janet Cunningham deserves a special thanks for her handling of the administrative aspects of this symposium and so do Dr. F. Alan Andersen and Dr. Andrija Kornhauser for their handling of the scientific aspects. Last but not least I thank the people at the Uniformed Services University of the Health Sciences for providing us with the excellent facilities to hold our program.

Let me now proceed with a short summary of the symposium. To begin, let me tell you how this symposium was born. Sometime last year, Dr. Andersen approached me and my colleagues at the FDA Office of Health Affairs (Science) and expressed concern about the fact that light is an important but often neglected variable in carcinogenesis bioassay experiments.

At the same time, my colleagues and I in the Office of Health Affairs (Science) were hearing that in cancer bioassays the position of the animal cage relative to the sources of illumination was an important determinant of the outcome of the study. Dr. Andersen and we at the FDA Office of Health Affairs (Science) agreed that agency scientists should be made aware of the effects of light on the outcome of carcinogenesis bioassays. Subsequently, Dr. Kornhauser visited my office with a request for help to fund a research proposal to study the toxic interactions of light and chemicals. Having no money to offer in support of Dr. Kornhauser's research, I offered instead to support this symposium, and Dr. Andersen and Dr. Kornhauser were enthusiastic at the opportunity. Thus the dedicated efforts of Dr. Andersen and Dr. Kornhauser converted an idea to reality.

Now, what did we learn yesterday and today? First, we learned that in experiments with whole animal systems and with systems of lower levels of aggregation, e.g., cells and macromolecules, we usually think we are dealing with the classic two-body system. Since yesterday, we have come to know better; we have come to know that we deal with a three-body system. But classical physics and quantum mechanics say that three-body systems present much more complex problems compared to the problems presented by the two-body system. The three-body system provides for greater variability in the experimental results that one can obtain and for a greater number of parameters that one needs to control.

The three-body system of concern here consists of the part of a living organism or the living organism itself, the chemical, and light. Further, we usually look at light as a single agent, which is not providing for the greater complexity of light. Light is many agents, as many agents as the distinct bands of wavelength that one wishes to consider. Also there are many living organisms and many distinct subdivisions of organisms as well. Finally, there are many, many chemicals. These chemicals may be drugs, industrial chemicals, natural chemicals, and chemicals produced by living organisms; they may be endogenous or exogenous to people. Yesterday and today we have heard that the effects produced by the interactions of these three bodies can be beneficial and, therefore, the system can be used for beneficial purposes. The effects of these interactions can be synergistic; they can be immediate; they can be delayed; they can be degenerative. They have many properties, some useful and some dreadful.

Yesterday and today we have learned that we can study interactions among two of the three bodies in the system and that we can then consider the influence of the third body as a perturbation of this, the two-body, interaction. We have heard of studies done at the molecular level, the subcellular level, the cellular level with mammalian cells or with microorganisms, or at the whole animal level. The purpose of this experimentation is to study the adverse effects that animals can suffer as a consequence of simultaneous or sequential exposure to light and chemicals.

The questions that arise in connection with a symposium such as this are: Where to next? What do the FDA and the other regulatory agencies need next? Outlines for some of the answers were formulated at the evening discussion session. We can work at a number of levels of living-system organizations. But matters that come before agencies such as the FDA involve decisions concerning limiting or permitting exposures of living systems to chemicals and light exposures that are either simultaneous or sequential. For the purpose of answering the regulatory questions, we are usually unable to integrate all the information obtained from studies at different levels of living-system organizations because of concerns over extrapolation.

So, even though we have a lot of good work being done in the field of photochemical toxicity, which parallels the more complex aspects of the work done in the field of chemical toxicity, we do not appear to link what scientific research can offer and what is needed to make practical regulatory decisions that have consequences in terms of economics, creature comforts, and the quality of life of individuals or groups of people.

Abbreviation used: FDA=Food and Drug Administration.

---

[1] Presented at the Seventh Food and Drug Administration Science Symposium ("Photochemical Toxicity: Toxic, Allergic, and Carcinogenic Aspects With Emphasis on Predicting Effects in Humans") held at the Uniformed Services University of the Health Sciences, Bethesda, Md., March 16–17, 1981.

[2] Office of Health Affairs (Science), Food and Drug Administration, Public Health Service, U.S. Department of Health and Human Services, 5600 Fishers Lane (HFY-31), Rockville, Md. 20857.

I will close, then, with a plea that applies both to researchers interested in photochemical toxicity as well as to those interested in chemical toxicity itself. Please remember in your research that knowing for the sake of knowledge or collecting information for the sake of knowledge is, of course, a very noble undertaking; however, look also into the practical aspects of the information that you collect and try to see whether you can pose questions and obtain answers that make possible the necessary everyday decisions of the FDA and other regulatory agencies.

REGISTRANTS

Lucile Adamson
Occupational Safety and Health Administration
519 Underwood St., N.W.
Washington, D.C. 20012

Frank Akin
Plough, Inc.
P.O. Box 377
Memphis, Tenn. 38151

Robert M. Albrecht

Correction

June 1981, vol 66, No. 6

In "The Causes of Cancer: Quantitative Estimates of Avoidable Risks of Cancer in the United States Today," by Richard Doll and Richard Peto, add the following after table 6 on page 1203: *Note*: Occupational exposure to phenoxyacid and/or chlorphenol herbicides (or their impurities) is a reasonably well-established cause of soft tissue sarcomas and perhaps lymphomas.

In the same article, page 1233, column 2, the following changes should be noted: 1) Delete "mammary" from line 10. 2) In lines 16–19, replace text between comma and period by "but 32 nonfatal spontaneous tumors arose among the 40 continuously fed mice, whereas only 4 arose among the 40 intermittently fed mice."

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

Second International Congress on Hormones and Cancer

Monte Carlo will be the site of this conference, sponsored by the International Association for Hormones and Cancer, to be held on September 18–23, 1983. The scientific program will include invited lectures and a limited number of free communications.

Information on speakers, the scientific program and committee, and satellite meetings may be obtained by writing to Dr. S. Iacobelli, Scientific Secretary, Laboratorio di Endocrinologia Molecolare, Università Cattolica del S.Cuore, L.go Gemelli, 8-00168 Rome, Italy (telephone: (06) 33054496 Telex 611330 unicatro).

Workshop Conference on Diet and Cancer

"Diet and Cancer, From Basic Research to Policy Implications" will be the subject of this conference to be held at Cornell University, Ithaca, New York, on August 16–18, 1982. Research, risk assessment, regulation, and public policy issues on the carcinogenic effects of nutrients will be addressed.

For further information please contact Mr. T. Colin Campbell, Division of Nutritional Sciences, Cornell University, MVR N-206, Ithaca, New York 14853.

Annual Symposium on Diagnostic Imaging

The Radiation Medicine Section of Brown University and the Department of Diagnostic Radiology of Rhode Island Hospital will cosponsor this symposium to be held at the Sheraton-Islander Inn, Newport, Rhode Island, on August 16–19, 1982. The symposium will emphasize use, techniques, comparisons, and trends among the diagnostic imaging modalities. Discussions will focus on the GI tract, renal system, retroperitoneum and pelvis, and head and spine.

Informal workshops will provide faculty-registrant interchange on nuclear cardiology, venography and pulmonary angiography, chest biopsy and chest CT, abdominal nuclear imaging and CT, noninvasive carotid imaging, CT of the head and spine, and ultrasound of the newborn head.

Approved accreditation is for 20 hours, Category I, AMA Physician's Recognition Award. For additional information please contact Educational Resources Associates, Inc., P.O. Box 369, Brookline, Massachusetts 02146 (telephone: 617-738-8859/8861).

Fourth International Symposium on Nasopharyngeal Carcinoma

The University of Malaya will sponsor this symposium to be held at the University of Malaya, Kuala Lumpur, Malaysia on September 27–29, 1982. The theme of the program will be the application of field and laboratory studies to the control of nasopharyngeal carcinoma.

For additional information please contact the Secretariat, NPC International Symposium, Department of ENT, Faculty of Medicine, University of Malaya, Kuala Lumpur 22-11, Malaysia.

Fifth Annual Bristol-Myers Symposium on Cancer Research

The Bristol-Myers Company will sponsor this symposium entitled "Chromosomes and Cancer: From Molecules to Man" to be held at the University of Chicago, Chicago, Illinois, on October 18–19, 1982. The symposium will focus on the consistent chromosome abnormalities that occur in human tumors and will explore the use of new techniques that can elucidate the role of chromosome abnormalities in malignant transformation.

Information regarding registration, for which there is no fee, may be obtained from Dr. Janet D. Rowley or Dr. John E. Ultmann, the University of Chicago Cancer Research Center, Box 444, 950 E. 59th Street, Chicago, Illinois 60637.

Twenty-Sixth Annual Clinical Conference

The University of Texas M. D. Anderson Hospital and Tumor Institute will sponsor this conference entitled "Current Controversies in Breast Cancer" to be held in Houston, Texas, at the Shamrock Hilton Hotel on

November 3–5, 1982. The conference will discuss the current status of therapeutic and diagnostic controversies surrounding breast cancer, and will focus on issues of limited mastectomy and irradiation; pathologic prognostic factors; breast cancer screening; long-term results on adjuvant chemotherapy; the value of biological markers; strategies for complete remission of metastatic disease; and second- and third-line therapies for advanced disease.

For additional information please contact Mr. Stephen C. Stuyck, Director, Public Information and Education, M. D. Anderson Hospital and Tumor Institute, Houston, Texas 77030 (telephone: 713-792-3030).

European Organization for Research on Treatment of Cancer Symposium

"Paraneoplasia: Basic Concepts and Clinical Aspects" will be the subject of this symposium to be held in Brussels, Belgium, on November 5–6, 1982. Invited speakers will lecture on endocrine paraneoplasia, neurological paraneoplasia, coagulopathies, and non-hormonal tumor markers. In addition, free communications of 10 minutes each are accepted. An abstract must be sent before September 30, 1982, to Dr. M. Staquet, Director, EORTC Data Center, rue Héger-Bordet 1, 1000 Brussels, Belgium.

Seating is limited and preregistration is recommended. For further information and registration contact Dr. M. Staquet at the above-mentioned address (telephone: [2] 538.57.90—telex: 22773).

Thirtieth Annual Scientific Meeting of the American Society of Cytology

Chicago, Illinois, will be the site of this meeting to be held at the Hyatt Regency Hotel, on November 8–13, 1982. The general outline of the scientific program will include a seminar for cytotechnology program faculties, cytology workshops, scientific papers and discussions, and a diagnostic cytology seminar.

The Continuing Education Program of the American Society of Cytology has been granted full approval by the Council on Medical Education of the American Medical Association. Physicians may earn credit hours for Category I, Physician's Recognition Award of the American Medical Association.

For additional information please contact Dr. Warren R. Lang, Secretary-Treasurer, 130 South 9th Street, Suite 810, Philadelphia, Pennsylvania 19107.

Sixteenth Midyear Topical Symposium of the Health Physics Society

The Rio Grande Chapter of the Health Physics Society will sponsor this meeting to be held at the Albuquerque Convention Center, Albuquerque, New Mexico, on January 10–14, 1983. "Epidemiology Applied to Health Physics" will be the subject of this meeting and invited speakers will participate in sessions dealing with: the relation of epidemiologic studies to radiation protection standards, epidemiological and statistical methods applied to research on health effects and radiation exposure, and risk estimation and its application to other areas.

Individuals who are interested should submit an abstract not exceeding 200 words by July 30, 1982 to Dr. Gregg S. Wilkinson, Chairman, Technical Program Committee, Epidemiology Group, Health Division, MS-404, Los Alamos National Laboratory, P.O. Box 1663, Los Alamos, New Mexico 87545.

Requests for information and registration materials should be sent to Mr. A. Wendell Holmes, 3800 Camino Don Diego N.E., Albuquerque, New Mexico 87111.

Urological Cancer Symposium

The USC Comprehensive Cancer Center, USC Division of Urology, USC Division of Postgraduate Medicine, and the Los Angeles Urological Society will sponsor this symposium to be held at the USC Health Science Campus, Los Angeles, California on January 14–15, 1983. The target audience includes urologists, medical oncologists, surgical oncologists, radiation oncologists, and general practitioners.

Interested persons should contact Ms. Katie Eisenberg, Regional Activities Program, 1721 Griffin Avenue, Los Angeles, California 90031 (telephone: 213-224-7416).

JNCI

Journal of the National
Cancer Institute

August 1982
Volume 69
Number 2

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $7.00. Subscription price for two volumes per year in the United States, $70.00; foreign, $87.50. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20816.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20816.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083-2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221-245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Merdicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3-10/Ann Intern Med 1979;90:95-99/Br Med J 1979;1:532-535/ or Lancet 1979;1:428-430).

Letters to the Editor

Trans Fatty Acids in Tumor Development

SIR: The Institute of Shortening and Edible Oils, Inc., submits the following comments about the recent paper by Awad[1].

1) Concerning experimental diets, comparison of the feeding of a triglyceride (olive oil) to the feeding of a free fatty acid (elaidic acid) is not a correctly controlled experiment. A properly controlled experiment would have been comparison of the feeding of olive oil with the feeding of elaidic acid in triglyceride form or the feeding of controls with a corresponding amount of free oleic acid. Furthermore, the experimental fats had substantial differences in fatty acid composition and therefore are not directly comparable. The reported levels of 16:0 in the olive oil and elaidic acid diets were 13.3 and 2.9%, respectively; total monoene levels, 60.0 and 7.8%, respectively; and 18:2 levels, 23.3 and 8.5%, respectively (table 1). Considering these large differences in non-*trans* acids between the two diets, the author cannot conclude that the reduced survival times of mice fed the elaidic acid diet were due to elaidic acid exclusively. It would be equally valid to conclude that the high levels of 18:2 (or 16:0) were *protective* of the animals fed the olive oil diet.

In addition, the feeding of free fatty acid of m.p. 44.5–45.5°C should be of concern because the higher melting fats usually are poorly digested. This fact alone is suggestive of a possible cause for the growth suppression (≈8% in 4 wk, table 2), even though the *trans*-fed mice ate about 17% more than did the olive oil group.

2) Some of the reported fatty acid composition data in table 1 are of questionable accuracy. For example, considering that corn oil comprised ⅔ of the total dietary lipid, the level of 18:2 in the elaidic acid diet should have been about 16.4%, yet the reported value was only 8.5%. Similarly, the expected level of 18:0 in the elaidic acid diet should have been about 0.5%, yet 2.6% was reported. These discrepancies suggest erroneous fatty acid analyses of the dietary fats.

If the actual level of 18:2 in the total fat of the elaidic acid diet were 8.5% as reported, then the level of 18:2 in this diet would have been about 0.6%, which would barely satisfy the essential fatty acid (EFA) requirement of the animals.[2] The animals fed this diet may have been borderline EFA-deficient, despite Dr. Awad's claims to the contrary. Thus the "host survival" data may reflect poor adaptation to the diet high in free fatty acid (as elaidic) and low in EFA.

3) The validity of the experiments involving thymidine uptake by the Ehrlich ascites tumor cells (table 3) may be questioned because there were no measurements of cell survival during the incubation period. Furthermore, the author did not report any cytological examination of these cells to determine if they were uniformly tumor cells or whether they also contained leukocytes which may be common in ascites tumor cells. Differences in proportions of tumor and nontumor cells in these ascites preparations might account for differences in thymidine uptake.

4) There is no correspondence between the in vitro thymidine uptake studies (table 3) and the weights of solid tumors 14 days after tumor inoculation (table 6). If *trans* acids were really stimulating tumor promotion as suggested by Dr. Awad (table 3), then the solid tumors in these animals should have been larger than those in the animals fed the olive oil diet. However, the data in table 6 indicate that "elaidic acid feeding did not significantly increase the weight of the solid tumor" after 14 days. No reason is offered for this apparent inconsistency. Borderline EFA deficiency may be an explanation since it has been shown that tumor cells also have minimum EFA requirements.[3]

The method used for measurement of tumor weight (difference in weight between tumor-bearing leg and opposite leg) may not be accurate since the presence of the tumor may lead to disuse atrophy of the tumor-bearing leg and perhaps hypertrophy of the noninvolved leg. Additionally, if the tumors are large, they may impair circulation or cause edema, so that weight differences may be misleading.

5) The Ehrlich ascites tumor is *not* a normal tumor for the mouse, in contrast to a tumor that might develop in response to treatment of the animal with a carcinogen. Thus Dr. Awad's study is somewhat artificial since it evaluates how mice fed particular diets handle one type of foreign tumor. Other tumor systems should have been evaluated for assessment of the general applicability of these results.

6) Among erroneous or misleading statements in this paper are the following:

a) *Trans* fatty acids are *not* "unnatural substances" as referred to by the author. They occur naturally in ruminant fats and thus have been in the diets of humans for centuries. Reliable estimates of *trans* acid intake by Americans, however, have not been published in spite of Dr. Awad's citation of Enig and co-workers'[4] reported intake range of 3.3–7% calories. The lower end of this range is supported by the recent work of Ohlrogge et al.,[5] which showed a close correlation between levels of isomeric fatty acids in the diet and in various human tissues and a range of 2.0–5.8% *trans* fatty acids in human adipose tissue. The 7% calorie figure is not supported by valid data and is probably too high.

b) Dr. Awad cited the recent report of Enig et al.[4] as indicating "possible negative health ramifications of the widespread ingestion of dietary *trans* acids" and "a possible linkage between the consumption of *trans* fatty acids and the incidence of cancer in the United States." However, Dr. Awad overlooked the fact that the work of Enig et al. was severely criticized in letters by Applewhite,[6] Bailar,[7] and Meyer.[8] Both the report by Enig et al. and the one by Dr. Awad failed to consider published studies in which high levels of *trans* fatty acids were fed to animals for long periods of time without any overall adverse effects.[9-12]

c) Dr. Awad's claim that ". . . the level of *trans* fatty acids used in these studies is lower than that present in some hydrogenated products . . ." is also incorrect. The *level* of elaidic acid *in the dietary fat* was 78%, and this is the crux of the argument. Had the author studied a diet truly parallel-ing the human diet, he should have reduced this value to less than 10% of the total fat. There are no commercial products containing 78% elaidic acid. The study of this pure compound as a free fatty acid adds confusion and does little to clarify a complex issue.

d) Dr. Awad's suggestion that "more studies . . . are needed . . . (to determine) . . . the safety of these unnatural (*trans* fatty acids)" ignores the many animal metabolic studies without any evidence of deleterious effects of *trans* fatty acids. The safety of hydrogenated fats and *trans*-monoenes for human use has been scrutinized repeatedly [cf. Applewhite[13]]. The closing quotation in Applewhite's article[13] best sums up the subject: "Trans, *trans*- 18:2 excepted, and with adequate linoleate intake, there is no strong evidence that they (*trans*-monoenes) are more harmful than any other fatty acid class."

Sir: This is a reply to Dr. Hunter's critique on my paper published in the July 1981 issue of JNCI.

1) The author is aware that oleic acid would be more appropriate as a control to elaidic acid than olive oil. However, our previous work[1] demonstrated that the commercial oleic acid (United States Biochemical Corp., Cleveland, Ohio) contains about 2.9% elaidic acid. The ideal control then would be a pure oleic acid, which is very costly for feeding, and thus our choice was limited to the oil (olive oil) from which most of the commercial oleic acid is obtained.

It is well known to the experimental scientist that it is difficult, if not impossible, to exactly duplicate the concentrations of all other fatty acids in the experimental diet to resemble those of the control unless pure fatty acids are used. The work of Carroll and Hopkins[2] argues against the possibility that high levels of 18:2 in the olive oil diet is protective against cancer. Their studies demonstrated that 20% sunflower oil diet induced more tumors in rats as compared with the number of tumors induced in rats fed 3% sunflower oil diet. Feeding the two experimental diets, as stated in the paper (table 2), revealed no significant effect for elaidic acid on body weight gain; we also stated that the increase in food consumption in animals fed elaidic acid as compared with the controls (olive oil diet) cannot be tested for significance since the individual observations of food consumption were not recorded.

2) The data presented for the fatty acid composition of the experimental diets were obtained by actual gas-liquid chromatography analysis after mixing the diets and were not derived by calculation from published chemical analysis for the fats used. Regarding reference 2 in Dr. Hunter's critique for the EFA requirements for mice, I would like to mention that Dr. Hunter unfortunately misread the statement in that reference. It was stated that "In the absence of specific studies in the mouse, the concentration of 0.3% linoleic acid, as recommended for the rat has been adopted." Thus our diets that contained double the recommended level should be more than sufficient, and the animals were not borderline EFA-deficient. *This was supported by the nonsignificant difference in growth rate between animals fed an elaidic acid or an olive oil diet.*

3) We tested the viability of tumor cells from animals fed elaidic acid diet or olive oil diet on several occasions, and it was found to be similar and ranged between 92 and 94%. This viability was not affected by incubation for 1 hour. Similar work by King and Spector[3] using in vitro incubation of Ehrlich ascites tumor cells under similar conditions demonstrated that this tumor can survive up to 4 hours without a decrease in its viability. The tumor cells were washed three times in saline after the blood cells were lysed by brief exposure to water. We checked for the presence of erythrocytes and leukocytes, and we could not detect any by light microscopy. This information was supplied to one of the reviewers of the JNCI *during the reviewing process of the paper.*

4) Measuring the size of the solid tumor by weighing its mass or by measuring its size would not be as accurate as biochemical indices to give ideas on the tumor growth and development. This could be the reason for not seeing differences in solid tumor mass by feeding the experimental diets.

5) It is well known that Ehrlich ascites tumor cell line has been originated in mice several decades ago by the use of chemical carcinogens. As Dr. Hunter stated in this regard, the issue of trans *fatty acids in the diet and how they affect normal and abnormal processes in the body is complex. For that reason we have decided to study* trans *fatty acids by using only one fatty acid at a time. In this particular study, we used the predominant* trans *fatty acid in hydrogenated vegetable oils, i.e., elaidic acid.*

6) a) There is a difference in the position of the double bond between the trans *fatty acids produced by rumen bacteria and those produced by industrial hydrogenation of vegetable oil ($18:1^{\Delta 11}$ vs. $18:1^{\Delta 9}$). This difference results in differences in fatty acid metabolism by the mammalian system.[4] For that reason, elaidic acid is considered* *to be unnatural. Studies by Ohlrogge et al.*[5] *reported differences in the concentrations of* trans *fatty acids in human tissues, and the values of 2–5.8% were reported for* adipose tissues. *There were no data in Ohlrogge and co-workers' paper for the* trans *fatty acid content of the human diet. These tissues were obtained at autopsy, and the dietary records for the deceased persons were not available.*

b) We are not aware of any other studies that have been done to examine trans *fatty acid's effect on tumor development, and it was not appropriate to discuss cancer with other diseases as Dr. Hunter suggested.*

c) For testing a hypothesis, especially with a rapidly growing tumor (14 days in the ascites form), one has to increase the level of the tested substance to greater than that present in the human diet. The increase was modest—11 versus 7% of dietary calories in human diet.

d) I believe that my paper contains useful information and further investigation in this area is warranted.

In conclusion, I can see that Dr. Hunter, as a representative for the Institute of Shortening and Edible Oils, Inc., is disturbed by the results of our studies since they could affect the marketing of their products. However, issues such as those related to diet and health of the American public should be subject to extensive independent investigation.

Multiple Myeloma Among Atomic Bomb Survivors in Hiroshima and Nagasaki, 1950–76: Relationship to Radiation Dose Absorbed by Marrow[1,2]

Michito Ichimaru, *M.D.*,[3] **Toranosuke Ishimaru**, *M.D., M.P.H.*,[4,5] **Motoko Mikami**, *M.D.*,[6]
and **Masako Matsunaga**, *M.D.*[6,7,8]

ABSTRACT—The relationship between atomic bomb exposure and the incidence of multiple myeloma has been examined in a fixed cohort of atomic bomb survivors and controls in the life-span study sample for Hiroshima and Nagasaki. From October 1950 to December 1976, 29 cases of multiple myeloma were confirmed in this sample. Our analysis shows that the standardized relative risk (RR) adjusted for city, sex, and age at the time of bombings (ATB) increased with marrow-absorbed radiation dose. The increased RR does not appear to differ between cities or sexes and is demonstrable only for those survivors whose age ATB was between 20 and 59 years. The estimated risk in these individuals is approximately 0.48 cases/million person-years/rad for bone marrow total dose. This excess risk did not become apparent in individuals receiving 50 rad or more in marrow total dose until 20 years or more after exposure.—JNCI 1982; 69:323–328.

Although leukemia has long been known to be a late effect of atomic bomb exposure (*1*, *2*), the incidence of multiple myeloma previously has not been found to be significantly elevated among atomic bomb survivors. On the basis of the autopsy material obtained by the ABCC in 1948–62, Anderson and Ishida (*3*) reported that the incidence of multiple myeloma among atomic bomb survivors in Hiroshima was slightly increased in the group exposed within 1,400 m of the detonation, as compared to the incidence in those individuals exposed beyond that distance; however, in the group within 1,400 m, there was only 1 multiple myeloma case. Up to September 1964, Ichimaru et al. (*4*, *5*) found 8 cases of multiple myeloma among the Nagasaki atomic bomb survivors, but they observed no unusual clinical features of the disease in these instances. These investigators did not examine the relationship of distance to risk of multiple myeloma. Yamamoto and Wakabayashi (*6*) reported an absence of evidence of radiation-induced bone tumors, including multiple myeloma in atomic bomb survivors in Hiroshima and Nagasaki during 1950–65. Nishiyama et al. (*7*) also made a study of malignant lymphoma and multiple myeloma in the same fixed cohort of atomic bomb survivors, but they could not demonstrate a significant excess risk of multiple myeloma in the heavily exposed. Thus for 20 years after the atomic bombings, no persuasive evidence of an excess of multiple myeloma among the survivors was found.

Inasmuch as 10 years have elapsed since Yamamoto and Wakabayashi (*6*) and Nishiyama and his colleagues (*7*) reported their findings, we thought it timely to examine again the effect of radiation on the risk of multiple myeloma, based on further follow-up of the cohort of atomic bomb survivors. Moreover, in 1980 an improved dosimetry, based on a new epicenter in Nagasaki proposed by Kerr and Solomon (*8*), became available for survivors belonging to the RERF fixed cohort. As a result of the formulas developed by Kerr (*9*) for bone marrow-absorbed dose per kerma dose conversion factors, bone marrow-absorbed dose is also now available for each atomic bomb survivor in this fixed cohort. These atomic doses may be changed, however, as the result of an ongoing review of atomic bomb dosimetry. Our risk estimates, although probably not the major conclusions presented in this paper, may require revision when that review has been completed.

On the basis of bone marrow-absorbed radiation dose, an analysis is presented herein of the multiple myeloma incidence among atomic bomb survivors and controls in the fixed cohort of the ongoing LSS (*10*) of the RERF in a 26-year period from October 1950 to December 1976.

MATERIALS AND METHODS

Subjects.—The death of 109,000 atomic bomb survivors and their controls in Hiroshima and Nagasaki has been under scrutiny since October 1, 1950, first at ABCC and later at RERF. In connection with this mortality surveil-

lance from 1961 to 1975, an intensive autopsy procurement program (*11*) existed, which was directed toward the original LSS sample (*12*) and excluded the extended part of the sample. Because the efficiency with which case findings of multiple myeloma were reported seems to differ between the original LSS sample and the extended portion, the present analysis is confined to the original LSS sample which totaled approximately 100,000 subjects.

Dosimetry.—In 1980 the RERF Department of Epidemiology and Statistics, using a new epicenter in Nagasaki and a standardized rounding procedure, recalculated the estimated atomic bomb radiation dose received by each survivor in this sample. The improved dosimetry system is called the "T65D revised system" or T65DR. If the total kerma for a survivor were calculated to be 600 rad or more and to avoid distortions arising from probable erroneous estimates (*13*), the investigators arbitrarily set the gamma dose for that survivor in Hiroshima at 439 rad and the neutron dose at 161 rad, whereas in Nagasaki the gamma dose was set at 587 rad and the neutron dose was set at 13 rad. Hiroshima had 165 such cases and Nagasaki had 138. There were 1,706 survivors for whom the estimated dose could not be calculated either because the information regarding their exposure was incomplete or the shielding configuration was unusually complex. Those survivors whose doses are unknown were excluded from the present analysis.

Individual bone marrow doses were calculated by means of Kerr's proposed formulas (*9*) for bone marrow dose per kerma dose conversion factors for Japanese atomic bomb survivors: $(D\gamma/K\gamma) = 0.56$, $(Dn/Kn) = 0.28$, and $(Dn, \gamma/Kn) = 0.067$, where $K\gamma$ = gamma kerma dose, Kn = neutron kerma dose, $D\gamma$ = marrow gamma dose converted by kerma gamma dose, Dn = marrow neutron dose converted by kerma neutron dose, and Dn, γ = marrow gamma dose converted by kerma neutron dose.

A degree of uncertainty still exists about the quality and quantity of radiation released by these two atomic bombs. Some recent estimates (*14, 15*) suggest that the total kerma was somewhat higher in Hiroshima and somewhat lower in Nagasaki than the present T65DR dosimetry system and that the present estimate of neutrons is grossly erroneous. If warranted by future dose assessments, the RR reported in this paper will be reanalyzed and subsequently reported.

Ascertainment.—The koseki system on which the mortality surveillance is based ensures virtually complete identification of deaths and causes of death in this fixed sample. All deaths ascribed to multiple myeloma among those individuals were screened. Pathologic studies intensively conducted under the ABCC–RERF autopsy procurement program since 1961 (*11*) provide supportive observations. Furthermore, almost complete screening of possible multiple myeloma from various medical sources was made through the Leukemia and Related Disorders Detection Program at

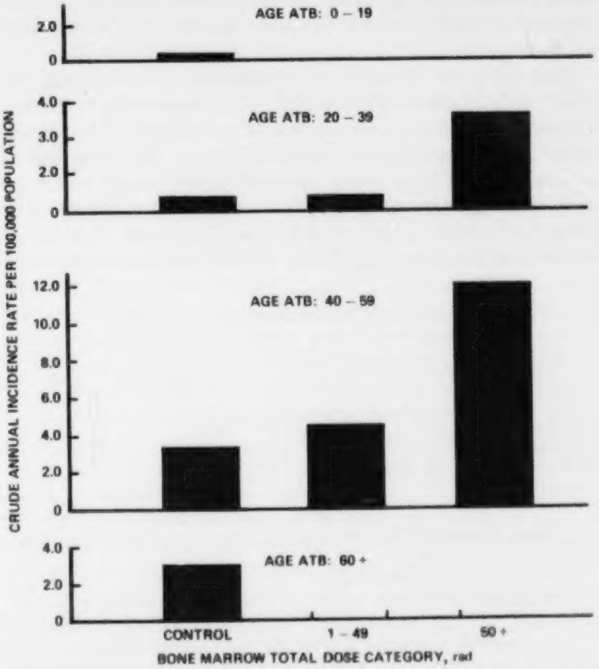
ABCC and later at RERF in Hiroshima and Nagasaki (*16*). With the aid of a standardized registration procedure, hematologists recorded all pertinent information available at the community hospitals and clinics to confirm a diagnosis of multiple myeloma. In the present analysis 3 hematologists (M. I., M. O. M., and M. A. M.) reviewed these records for possible multiple myeloma cases. Microscopic evidence of myeloma cells, laboratory tests of immunoglobulins, X-ray findings of bone, and autopsy findings were all used to establish the diagnosis. The final judgment was made by the senior hematologist (M. I.). Through the foregoing screening procedure, 35 cases of possible multiple myeloma were identified in the original LSS sample from October 1950 to December 1976. On the basis of available medical data, the diagnosis of multiple myeloma was accepted in 29 instances: 22 individuals who were exposed to the atomic bomb and 7 individuals who were NIC ATB.

Table 1 shows the distribution of atomic bomb survivors and controls in the LSS sample by city and marrow total dose. The sample consists of 97,544 persons—73,313 in Hiroshima and 24,231 in Nagasaki. Hiroshima NIC subjects were selected in 1950, 1951, and 1953; hence the observation periods differ from those for individuals who had been exposed to the atomic bomb. Hiroshima survivors, at least until recently, have been assumed to have received mixed gamma and neutron exposure at all dose levels, whereas Nagasaki survivors received largely gamma exposures except at the higher dose levels, but even in Nagasaki the neutron exposure was small when contrasted with that in Hiroshima.

RESULTS

Annual Incidence Rate of Multiple Myeloma in LSS Sample by Marrow Total Dose

Table 2 shows the crude and standardized annual incidence rates adjusted for city, sex, and age ATB for 3 dose



TEXT-FIGURE 1.—Crude annual incidence rate of multiple myeloma (by age ATB and total marrow dose) for atomic bomb survivors and controls in the LSS sample, Oct. 1950–Dec. 1976, Hiroshima and Nagasaki.

classes. The RR significantly increases with marrow total dose after adjustment for city, sex, and age ATB ($P<0.01$), as judged by an extension of the Mantel-Haenszel procedure (*17*). The standardized RR is approximately 3 among those individuals who received 50 rad or more in marrow doses, as compared to the RR for controls. The RR was calculated by Miettinen's procedure (*18*).

Table 3 gives the specific annual incidence rate by sex, city, and age ATB for 3 dose classes. The RR tends to increase with dose for both sexes in both cities in the 20- to 59-year age ATB group. When the data were examined by dividing them into 12 categories (3 dose groups and 4 age ATB groups), the number of cases in each category was small. However, a dose effect is not evident among those individuals whose age ATB was less than 20 years or 60 or more years, although the risk tends to increase in the control group with age. Text-figure 1 shows the age ATB-specific annual incidence rate by dose for the 4 age ATB groups, and apparently the dose effect does differ.

The distribution of age at onset of the 29 confirmed cases in the present study is shown in table 4. Clearly, multiple myeloma occurs frequently after 60 years of age, and thus the failure to see an effect in the under-20-year group may merely reflect the fact that these individuals have not yet reached the age at which multiple myeloma is more prone to develop.

The apparent absence of a radiation effect among the oldest individuals (≥60 yr of age ATB) is thought to be due to other reasons. Because a dose effect is evident only among those individuals 20–59 years of age ATB, a regression analysis based on a linear dose-response model was conducted for this group to estimate the risk of multiple myeloma per million population per year per rad. Tables 5–7 summarize the linear regression analysis for dose response of multiple myeloma among atomic bomb survivors and controls whose age ATB was between 20 and 59 years in the LSS sample. Tables 5 and 6 present summaries of the results of fitting two linear dose-response models to these data. Model I (table 5) assumes a linear dependence on marrow total dose, and model II (table 6) assumes a linear dependence on γ-rays and neutrons, separately. The analysis revealed that model I fits the data well (small chi-square and large-tail probability), and the regression coefficient is suggestively significant ($0.05<P<0.10$). The estimated risk is approximately 0.48 cases (SE, 0.29)/million P-Y/rad for bone marrow total dose. When a dose-response model was tested that assumes a linear dependence for both γ-rays and neutrons (table 6), the model again fit the data well. However, the regression coefficients for both γ-rays and neutrons were not significantly different from zero nor even suggestively so.

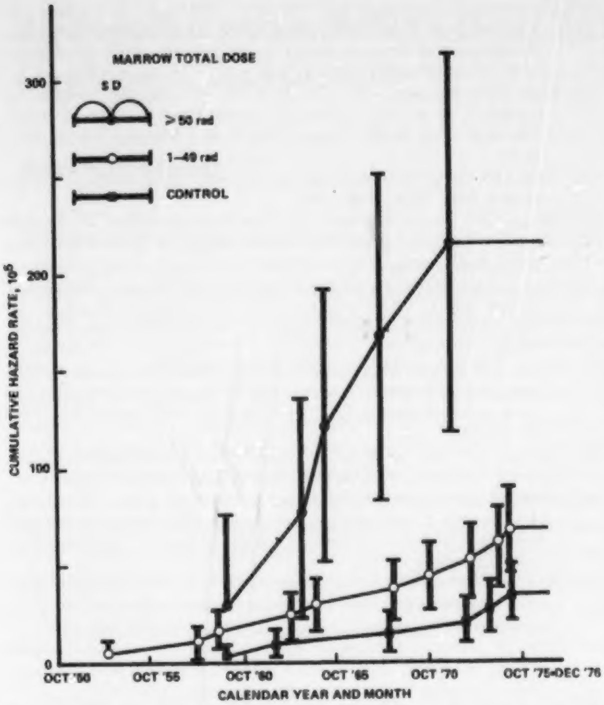
Cumulative Hazard Rates of Multiple Myeloma By Three Marrow Dose Groups

We used a simple graphical method called "hazard plotting" (*19, 20*) to compare the cumulative risk of multiple myeloma in 3 dose groups in relation to years after exposure. Text-figure 2 shows the cumulative hazard rates for individuals aged 20–59 ATB in 3 marrow dose groups (≥50, 1–49, and <1 rad) from October 1950 to December 1976. An increased risk in the high-dose group (≥50 rad) does not become apparent until 20 years after exposure.

Clinical Features of Multiple Myeloma

Although the available records on the clinical course of multiple myeloma cases have limited value and the observed number of individuals in the high-dose group is small, the clinical and autopsy findings and immunoglobulin properties are not unique for the high-dose survivors when compared to those for the control group. The type of immuno-



TEXT-FIGURE 2.—Cumulative hazard rates for atomic bomb survivors and controls (aged 20–59 yr ATB) in the LSS sample, Oct. 1950–Dec. 1976, Hiroshima and Nagasaki. The controls, selected in Oct. 1950, were individuals who had received <1 rad radiation or were NIC ATB.

globulin seen in myeloma was recorded for 4 of 17 patients (24%) in whom onset of the disease occurred before 1971 and for 5 of 12 patients (42%) in whom onset occurred in 1971 or later, which suggests that the techniques for the diagnosis of multiple myeloma have improved in recent years. A clinical diagnosis of multiple myeloma could not be confirmed by autopsy in 2 of 6 possible cases.

DISCUSSION

Only a few studies exist on the relationship of death from multiple myeloma to occupational long-term, continuous low-dose, ionizing radiation exposure. Lewis (*21*) noted that the observed mortality from multiple myeloma among American radiologists was significantly higher than expected. In 1977, Mancuso et al. (*22*) reported an excess mortality due to bone marrow cancers, including myelomas and myeloid leukemias, among Hanford workers who received radiation exposure during the manufacture of radioactive substances. Subsequently, Gilbert and Marks (*23*) and Hutchinson et al. (*24*) reanalyzed these data. Both analyses indicated a significant relationship of radiation exposure to cancer of the pancreas and multiple myeloma among Hanford workers who received significant radiation exposure, but no evidence of a dose effect was seen for cancers of other sites including those more typically associated with radiation exposure, such as myeloid leukemia and lung cancer. In 1977, independently of the Hanford studies, we initiated the present study based on the Leukemia Registry at RERF because of our interest in examining whether an induction of multiple myeloma among atomic bomb survivors could be demonstrated 20 years after exposure to the bomb. Earlier studies on the incidence of multiple myeloma among atomic bomb survivors had failed to demonstrate a significantly increased risk with dose (*3, 6, 7*).

The present analysis was conducted on a fixed cohort of survivors and controls 5–31 years after exposure; thus data on the entire life-spans of the subjects in this cohort were not examined. Evaluation of the latent period was complicated by the fact that the number of cases is not large enough to permit examination of the development pattern of radiation-induced multiple myeloma in relation to age ATB. By the end of 1976, attrition due to death was about 28% for the entire cohort: Death had occurred in approximately 98% of the individuals aged 60 years or more ATB, in 60% of those aged 40–59 years ATB, in 15% of those aged 20–39 years ATB, and in 5% of those aged less than 20 years ATB. Thus further investigation of this cohort will not result in the detection of any new cases among individuals aged 60 years or more ATB in the high-radiation-dose category.

Our analysis suggests that the latent period of radiation-induced multiple myeloma is longer the younger the age ATB, except for those survivors whose age ATB was 60 years or more. The pattern of development of radiation-induced leukemia among atomic bomb survivors suggests an earlier development of leukemia in the younger age ATB groups and later development of the disease in older age ATB groups (*2, 25*). Thus the pattern of development (latent period and effect of age ATB) of radiation-related multiple myeloma appears to differ from that of leukemia.

A relationship of multiple myeloma mortality to radiation exposure in the fixed cohort of atomic bomb survivors was not reported until 1974 (*26*); however, Kato and Schull (*27*) recently noted, from death certificate information for the period between 1950 and 1978, an excess risk of multiple myeloma mortality in atomic bomb survivors.

Although the present analysis failed to produce a significance dose-response function for the incidence of multiple myeloma in relation to gamma and neutron doses separately, the risk of multiple myeloma among survivors whose age ATB was 20–59 years is estimated to be about 0.48 cases/million P-Y/rad for marrow dose under a linear dependence on total marrow dose. Risk estimates for excess mortality from multiple myeloma in Hanford workers have not been reported due to the small number of cases (*22–24*).

Excess multiple myeloma mortality has been reported among employees in nuclear processing plants at Hanford. The original report by Mancuso et al. (*22*) showed an increased mortality from bone marrow cancers, including myeloid leukemia and multiple myeloma, and from pancreas cancer and lung cancer. Gilbert and Marks (*23*) and Hutchinson et al. (*24*) subsequently reanalyzed the data on these workers and reported that the excess proportional deaths from cancer of the pancreas and multiple myeloma occurred in employees who received significant radiation from occupational exposure, but these investigators failed to demonstrate the effect of radiation on those cancers that are more commonly associated with radiation exposure, such as myeloid leukemia and lung cancer. Thus the results of Mancuso et al. now seem to be discounted.

Cuzick (*28*) recently reviewed multiple myeloma mortality in several cohort studies of persons exposed to radiation. He reported that an excess in incidence of myeloma was found in most cohorts but that the incidence was negligible in groups irradiated for uterine neoplasms. Most of the radiation-related cases of multiple myeloma occurred 15–25 years after exposure.

Although the incidence of multiple myeloma was significantly elevated among heavily exposed persons in our study, the observed number of cases in the high-radiation-dose group was small, and the clinical findings, immunoglobulin properties, and autopsy findings were not unique when compared to the data for the control group. The cases we studied were identified by retrospective review of available records accumulated over the 3 postwar decades. Unfortunately, these records are not uniformly detailed insofar as the clinical course of the disease is concerned, and an immunoelectrophoretic examination was not done routinely. The older cases, in contrast to the more recent ones, do not have records of immunological laboratory tests. However, despite improvements over the years in techniques for the diagnosis of multiple myeloma, it is unlikely that the newer immunological laboratory tests for the diagnosis of multiple myeloma create a bias in case detection by dose.

Myelomatous cells are considered to be of B-cell lineage, as are malignant neoplasms of the lymphatic system. They differ, however, from the malignant lymphoma cells which proliferate in lymphatic tissues, primarily in the lymph nodes. Spontaneous myeloma is a disease frequently found in advanced age groups, and possibly an immunoinsufficiency due to aging contributes to the development of this disease together with the late effect of atomic bomb exposure. The mechanism for development of radiation-induced myeloma apparently is different from that for radiation leukemogenesis. According to reports of follow-up studies on patients who received radiotherapy for ankylosing spondylitis and tinea capitas, bone tumors can be induced by radiation exposure (*29–31*). In those studies, multiple myeloma was not classified as a bone tumor. We also consider multiple myeloma to be different from malignant neoplasms of the bone, although an earlier report by Yamamoto and Wakabayashi (*6*) showed a negative effect of radiation for the induction of bone tumors including multiple myeloma.

Possible Association of Radioprotective and Chemoprotective Aminophosphorothioate Drug Activity With Polyamine Oxidase Susceptibility[1,2]

Joseph M. Gaugas[3,4,5]

ABSTRACT—The aminophosphorothioate drug *S*-2-(3-aminopropylamino)ethylphosphorothioate (WR-2721) is both radioprotective and chemoprotective, with potential clinical use in cancer therapies. These distinct properties may be associated with its catabolism by polyamine oxidase (EC 1.4.3.4), which is found in varying amounts in different body tissues. Unfortunately, the metabolite is probably a cytotoxic aldehyde, but it should be detoxified in vivo following adduction with tissue sulfhydryls. Whether conversion and adduction benefit or hinder pharmacologic activity is not known, inasmuch as aldehydes may reduce oxygen-dependent free radicals generated by irradiation of tissues. *S*-2-(3-aminopropylamino)propylphosphorothioate was similarly a substrate for polyamine oxidase, and the product was cytotoxic. Other aminophosphorothioates [*S*-2-(4-aminobutaneamino)ethylphosphorothioate, *S*-2-(5-aminopentylamino)ethylphosphorothioate, and *S*-2-(4-aminobutaneamino)propylphosphorothioate] were poor substrates and less radioprotective.—JNCI 1982; 69:329–332.

Radiation injury of normal tissues contiguous to solid tumor is a major problem in radiotherapy. Injury imposes a limitation on the size of tumor suitable for radical radiotherapy, restricts dosage, and a course of radiotherapy is rarely repeated should regrowth of the tumor occur [(*1*) and references therein].

For decades it has been well known that both biogenic and synthetic sulfhydryls, such as L-cysteine, β-mercaptoethylamine, and 2-aminoethylisothiourea, afford significant protection of animals against lethal-dose radiation. Administration of the aminophosphorothioate drug *S*-2-(3-aminopropylamino)ethylphosphorothioate (WR-2721) reduced the radiosensitivity of many body tissues and evoked a 2.6-fold increase in the whole-body dose of radiation lethal for 50% of mice by day 30 ($LD_{50/30}$) (*2*).

Undoubtedly, need exists in the cancer clinic for drugs that preferentially protect normal rather than neoplastic tissue against radiation injury. The aminophosphorothioate drugs (particularly WR-2721) have been extensively studied in animals and fulfill such criteria (*2–8*), because WR-2721 does not penetrate as quickly into many types of tumor as it does into normal tissues (except the central nervous system) (*4–6*). More recently, WR-2721 was also shown to preferentially protect normal rather than neoplastic tissue against the side effects of alkylating agents (*7*), with implications for its use as an adjunct in cancer chemotherapy (*8–10*).

We noticed that the aminophosphorothioate drugs of the WR series listed in table 1 possess the substrate requirement (*11*) for PAO. PAO is found mostly in the pancreas, liver, spleen, and kidney (*12*) as the PAO–flavin form (*11*) and in ruminant sera as the PAO–pyridoxal form (*13*). PAO converts biogenic polyamines, spermidine, and spermine to labile aminoaldehydes which are extremely cytotoxic [(*14*) and references therein]. WR-2721 was similarly converted, possibly to a cytotoxic thiolaminoaldehyde [i.e., aldehyde of *N*-(2-mercaptoethyl)-1,3-diaminopropane (WR-1065)] (*15*). In this preliminary investigation any association between PAO susceptibility and radioprotective ability was noted for certain aminophosphorothioate drugs in the WR series. In addition, the in vitro cytotoxicity of the drugs was evaluated.

MATERIALS AND METHODS

Cell culture bioassay.—Cells (Bri8 human B-lymphocytes) were seeded at low density in 1.0-cm^3 cultures (in triplicate) of RMPI-1640 medium, supplemented with L-glutamine and antibiotics (Flow Laboratories Limited), 10% FCS (Sera-Labs Ltd.), which is known to have such endogenous PAO activity, and catalase (Sigma London Chemical Co., Ltd.), as fully described elsewhere (*14, 15*). After 4 days' incubation of the cultures at 37°C in an atmosphere of 5.0% CO_2 in air, the cells, which had a doubling time of about 21 hours, were dispersed with isotonic EDTA buffer and counted in an automatic Coulter Counter. PAO activity could be completely ablated by addition of 3-hydroxybenzyloxyamine (10 μ*M*) with no effect on cell proliferation (*14, 15*). Aminophosphorothioates were solubilized just before their addition to the cultures on day 0 to minimize any autodephosphorylation (*16*). Sterile precautions were taken throughout the procedures. The ability of the aminophosphorothioates to inhibit cell proliferation in the presence of FCS, FCS with added purified PAO (Miles Laboratories, Ltd.), and FCS when its PAO activity had been ablated was measured, and the results were compared (table 1).

PAO substrate assay.—The PAO susceptibility of substrates (spermidine and aminophosphorothioates) was assayed by a colorimetric method (*17*), as well as by the foregoing bioassay.

ABBREVIATIONS USED: FCS=fetal calf serum; PAO=polyamine oxidase.

[d] FCS has endogenous PAO activity equivalent to 4.0 $\mu g \cdot cm^{-3}$ of the purified PAO (29.2 $U \cdot g^{-1}$, where 1.0 U converted 1.0 $\mu mol \cdot min^{-1}$ benzylamine at pH 7.2).

[e] Inactivated in FCS by addition of 3-hydroxybenzyloxyamine (10 μ*M*).

[f] 10 $\mu g \cdot cm^{-3}$ PAO. NT = not tested.

[g] Determined by colorimetric assay (also by rough bioassay guide obtained by comparison of results in columns 3, 4, and 5).

[h] HTD = highest tolerated dose at which test mice survived. HTD_{50}, indicates 50% survival; HTD_{25}, 20–49% survival; $HTD_{12.5}$, 20% survival; $HTD_{6.25}$, <20% survival. Forty mice at each HTD level were exposed to 8.0 Gy whole-body radiation. ± = few survivors, (T) = some deaths due to interaction of drug and radiation.

[i] Some detoxification due to PAO activity of the FCS.

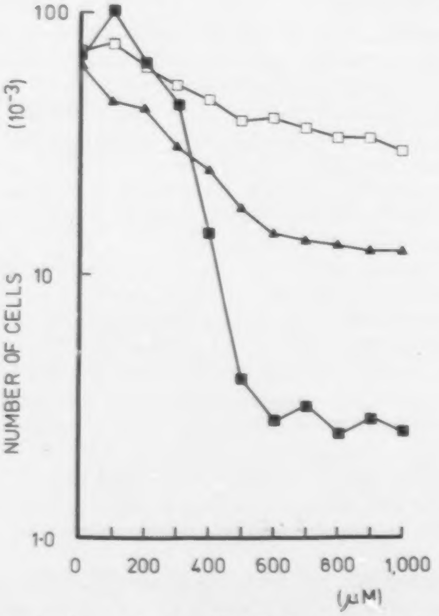
[j] *S*-2-(5-aminopentylamino)ethylphosphorothioate.

RESULTS

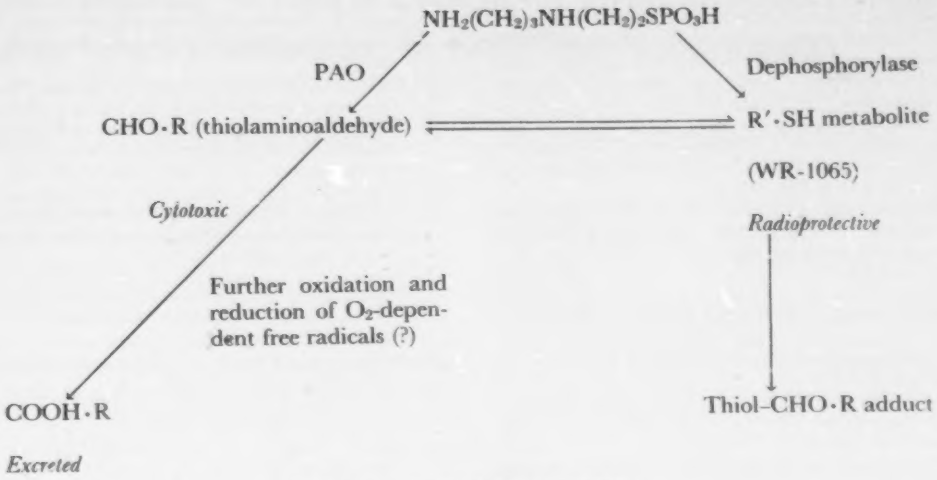
The antiproliferative or cytotoxic effects of WR-2721, WR-1065, and *S*-2-(3-aminopropylamino)propylphosphorothioate (WR-44923) on cultured cells are shown in text-figure 1 and table 1; the effects of other aminophosphorothioates are summarized in table 1. Cytotoxicity of WR-2721, WR-1065, and WR-44923, but not of the other compounds, was substantially increased when the drugs were oxidized by PAO. In contrast, *S*-2-(4-aminobutaneamino)ethylphosphorothioate (WR-2822) and *S*-2-(4-aminobutaneamino)propylphosphorothioate (WR-80855) were poor substrates for PAO, and they also afforded significantly less radioprotection (table 1) (*6*). The degree of cytotoxicity of the polyamine-like drugs in the WR series varied considerably when the PAO (in FCS nutrient) was completely inhibited by 3-hydroxybenzyloxyamine. More importantly, there apparently is an association between the radioprotective potency and PAO susceptibility of the drugs, as measured by the antiproliferative effect of the drugs when oxidized and when the radioprotective ratings of the drugs are considered (table 1).

The cytotoxicity of the oxidized aminophosphorothioate drugs generally could be prevented by addition to cultures of 2 m*M* of the sulfhydryls L-cysteine, reduced glutathione, and DL-homocysteine, as had been reported previously for WR-2721 (*14*). Note that dephosphorylation of WR-2721 in solution at neutral pH was completed within 2 hours, as determined by pH change (*14*, *16*). Therefore, the relative loss in WR-2721 toxicity beyond approximately 600 μ*M* probably was due to adduction of the thiolaminoaldehyde product with the dephosphorylated (i.e., free sulfhydryl) product. This finding of autodephosphorylation agrees with recently published data (*16*).

As determined by colorimetric assay, the relative PAO substrate activity of WR-2721 and WR-44923 was 10.5% relative to spermidine as 100%; the activity of the remaining drugs in the WR-series (table 1) was not detectable.



TEXT-FIGURE 1.—Arrest of cell proliferation by WR-2721 (▲) and WR-44923 (■) and its partial prevention by PAO inactivation by added 3-hydroxybenzyloxyamine (□). Similarly, partial prevention of WR-2721 cytotoxicity was obtained by PAO inactivation [*see* (*15*)]. Results are expressed as mean cell counts (triplicate cultures) after 4-days' growth; coefficient of variation, <10% of mean.



TEXT-FIGURE 2.—Catabolism of WT-2721.

DISCUSSION

The radioprotective ability of aminophosphorothioates probably is due to slow in vitro dephosphorylation of the R·SPO$_3$H moiety to R·SH (i.e., WR-1065) (*15*, *16*), which can scavenge the tissue-damaging free radicals generated by radiation (*2–8*). Substitution of the R·SPO$_3$H moiety with either R·SH or R·SSO$_3$H afforded less radioprotection of mice (*6*).

Adduction of oxidized aminophosphorothioates (thiolaminoaldehydes) with nonprotein sulfhydryls (e.g., L-cysteine), which abound in body tissues, probably causes an in vivo detoxification. The radioprotective efficacy of the adduct has yet to be ascertained.

Presumably, the catabolism of WR-2721, for example, proceeds as in text-figure 2, with a stable end product (R·COOH) excreted into the urine. Since PAO distribution in tissues varies considerably, with low levels in lungs and muscle (*12*), the extent of the catabolism of WR-2721 and WR-44923 by both PAO and dephosphorylase could influence their radioprotective activity for different tissues. Combined administration of a PAO inhibitor drug (pyridoxal and/or flavin cofactor inactivators) with WR-2721 or WR-44923 might spare the radioprotective capability of these WR drugs while decreasing their toxicity. This expediency may benefit tumor radiotherapy and tumor chemotherapy with alkylating agents.

Since aminoaldehydes are potent reducing agents (*14*), they may reduce tissue-damaging, oxygen-dependent free radicals generated by tissue irradiation. This possibility is currently under investigation, and preliminary data show that the aldehyde of WR-2721 is a much more powerful reducing agent than the aldehyde of oxidized spermidine (Gaugas JM, Dewey DL, Stratford MR, Minchington AI: Unpublished data). Therefore, if both the CHO and SH moiety of a WR-2721 metabolite are radioprotective to some degree, then the kinetics of metabolite production and lability could account for differences observed in the radioprotective ability of WR-2721 and closely related compounds (e.g., those listed in table 1), which may or may not be more susceptible to PAO. The chain length of aldehydes determines whether they exist in a free (RCHO) or hydrated (RCH(OH)$_2$) state (*18*). It is not known which of the two states would function better in vivo as reducing agent for certain free radicals.

Phase I clinical trials for WR-2721 in the United States have progressed to the stage where the results are being reported to the National Cancer Institute in preparation for a Phase II radiotherapy trial of WR-2721 in which dosage levels known to be safe will be used (*9*, *19*, *20*). Those doses would not give the full degree of radioprotection, however, that would be obtainable with the higher doses already proved satisfactory in laboratory animals (*2*, *9*, *19*, *20*).

So far I am able to conclude from my work with aminophosphorothioate drugs [*see also* (*15*)] that their deamination by PAO may somehow facilitate their radioprotective efficacy. If so, it should be possible to design protective drugs that would be more susceptible than WR-2721 or WR-44923 to PAO activity and that would be better prospects for clinical use. If not, it should be possible to modify the structure of WR-2721 or WR-44923 to make them insusceptible to PAO and, as a consequence, less toxic. Then those of us working in this field could decide whether or not the in vivo PAO catabolism of aminophosphorothioates increases their pharmacologic efficacy and whether further development of drugs is necessary.

Search for Evidence of Feline Leukemia Virus Infection in Humans With Leukemias, Lymphomas, or Soft Tissue Sarcomas[1,2,3]

Peter P. Sordillo, *M.D.*,[4] **R. Pincow Markovich**, *B.S.*,[4] *and* **William D. Hardy, Jr.**, *V.M.D.*[4]

ABSTRACT—Two-hundred and thirty-nine patients, including 66 with soft tissue sarcomas and 173 with hematologic cancers, were investigated for evidence of infection with feline leukemia virus (FeLV). Included in this group were 2 patients with acute lymphocytic leukemia who had lived in the same household with leukemic cats. None of the patients demonstrated measurable levels of neutralizing antibody to FeLV or had detectable FeLV antigens in peripheral blood normal leukocytes or leukemic cells. In a smaller number of patients, there was no evidence of antibody to FOCMA or of FOCMA on tumor cells in the bone marrow.—JNCI 1982; 69:333–337.

In 1969, natural field isolates of FeLV were found to be able to infect and replicate in human cell cultures (*1*). This observation and the finding, in 1973, that FeLV is spread contagiously among cats via the saliva brought concern that FeLV might be able to infect and cause disease in humans (*2–6*). FeLV is oncogenic in a species other than the cat. When inoculated into newborn puppies, FeLV can induce virus-positive lymphosarcomas (*7*). Since FeLV can infect and replicate in human lymphoid cells in culture, it is possible that FeLV induces lymphoid tumors in humans (*8, 9*). Experimental challenge of humans with FeLV can, of course, never be done; thus the possible oncogenicity of FeLV in humans can only be determined by long-term observation of individuals living with infected cats or by examination of human patients with tumors for evidence of FeLV.

Several oncoviruses (RNA tumor viruses) have been transmitted naturally from one species to another. FeLV originated in ancestral rats and spread to the ancestor of the pet cat; the gibbon ape leukemia virus originated in Asian mice and spread to Asian gibbon apes; and the bovine leukemia virus originated from an unknown and possibly extinct species and spread to cattle (*10, 11*). In each of the recipient species, the viruses are spread contagiously and induce neoplastic disease. Due to these observations and concerns and because FeLV is probably the only known tumor virus of any animal to which humans are frequently and intimately exposed, epidemiologic and seroepidemiologic studies have been done to determine if FeLV is associated with disease in humans (*12, 13*).

Sarcoma viruses of birds, mice, rats, cats, and subhuman primates are derived by replication competent leukemia viruses of each species recombining with a host cellular gene (*14*). The resulting replication-defective sarcoma virus is highly oncogenic in the host species and often in other species as well. The FeSV, which are derived by recombination of FeLV with cat cellular *onc* genes, induce virus-producer sarcomas in young pet cats (*15, 16*). In addition, FeSV can induce, by experimental inoculation, virus-nonproducer tumors in dogs, cattle, sheep, and primates [for review, *see* (*16*)]. However, although cells transformed by FeSV in nonfeline species often do not produce infectious FeLV or FeSV, they do possess FeLV structural antigens, proteins of 15,000 12,000, and 27,000 daltons (p15, p12, p27) (*17*).

Thus we undertook a study using the IFA test for FeLV antigens and serologic tests to determine if humans with hematologic tumors or with sarcomas have antibody to FeLV antigens or to the FOCMA, an FeLV- and FeSV-induced tumor-specific antigen (*18–22*). A total of 239 patients (192 adults and 47 children) with various types of cancer and seen at Sloan-Kettering Institute for Cancer Research between May 1, 1978 and December 31, 1980 were tested for neutralizing antibody to FeLV. Of these patients, 191 were also tested for FeLV antigens and 20 for antibody to FOCMA. In addition, tumor cells from the bone marrows of 20 of these patients were tested for FOCMA.

MATERIALS AND METHODS

IFA test for FeLV antigens (*18*).—Blood smears from each patient were fixed for 8 minutes in absolute methanol, and 0.05 ml rabbit anti-FeLV group-specific serum was placed in a small well made with a marker pencil on each slide. The smears were incubated at 37°C for 1 hour and then washed twice for 5 minutes in PBS. We then placed 0.05 ml goat anti-rabbit IgG–FITC conjugate (Miles Laboratory, Elkhart, Ind.) (1:80) in each well. After incubation at 37°C for 1 hour, the smears were washed. Then they were counterstained with Evans' blue for 2 minutes, washed twice in PBS, and dried. Control, FeLV-infected cat blood smears were tested along with all human blood smears. The slides were examined under a Zeiss UV microscope.

Absorption test for FOCMA (*21*).—We mixed 0.2 ml bone marrow cells ($\approx 3 \times 10^8$ cells/ml) with 0.2 ml cat serum containing FOCMA antibody at its 50% end point dilution

---

ABBREVIATIONS USED: FeLV=feline leukemia virus; FeSV=feline sarcoma virus(s); FITC=fluorescein isothiocyanate; FLF=feline lung fibroblasts; FOCMA=feline oncovirus-associated cell membrane antigen; IFA=immunofluorescent antibody; LTR=long terminal repeats; PBS=phosphate-buffered saline; SN=serum neutralizing.

(1:64). For comparison, 0.2 ml serum without cells was handled exactly as the samples being absorbed. All were incubated on ice for 1 hour and at room temperature for 1 hour. Following incubations, all samples were centrifuged for 20 minutes at 2,000 rpm. Supernatants (sera) were aliquoted equally into three portions and stored at −70°C. A direct test for expression of FOCMA was done as described in the test for FOCMA antibody, but we used the absorbed serum. Lack of absorption of the FOCMA antibody indicated a lack of FOCMA expression in the human cells tested.

Test for SN antibody to FeLV.—The FLF cells (FLF-3) in 0.05 ml culture medium (2.5×10^5 cells/ml) were placed on multispot fluorescent slides (Hendley Co., Essex, England) and allowed to attach to the wells by incubation of the slides for 24 hours at 37°C. Serum from each patient was heat inactivated at 56°C for 30 minutes. Dilutions of 1:2 and 1:10 of the sera were mixed with 40 infectious units of FeLV serotypes A and B. For the infection control, a mixture of equal volumes of media and 40 infectious units FeLV was used. The neutralization control consisted of 1:30 dilution of cat serum containing a titer greater than 1:30 of SN antibody mixed with 40 infectious units FeLV and media. The test sera and FeLV mixtures and controls were incubated for 1 hour at 37°C in CO_2. The medium was then removed from the wells of the seeded slides, leaving FLF monolayers attached to the wells. One drop (0.05 ml) of each test serum-virus mixture was placed in its appropriate well and incubated for 1 hour at 37°C to allow for FeLV attachment to the susceptible FLF cells. The serum–virus mixtures were then replaced with fresh medium and incubated for 3 days at 37°C. After incubation, the slides were washed and fixed for 8 minutes in absolute methanol. The IFA test for FeLV as previously described was then done on the cells. The presence of any fluorescent-positive cells indicated that SN antibody to FeLV was not detectable at the dilution of serum tested.

Test for FOCMA antibody (20, 21).—FeLV-positive feline lymphosarcoma cells (FL-74) were washed three times in medium 199 and centrifuged for 5 minutes at 400 rpm and for 5 minutes at 800 rpm (*23*). From each patient 0.05 ml serum at dilutions of 1:4, 1:16, and 1:32 was mixed in 15-ml tubes with 0.05 ml cells (15×10^6 cells/ml). A mixture of 0.05 ml cells and 0.05 media was used as a conjugate control. As a positive FOCMA antibody control, a cat serum containing a titer of 1:64 or greater of FOCMA antibody was used at the same dilutions as the human serum being tested. The FL-74 cells were incubated on ice for 30 minutes and then washed twice in medium. Following the second wash, the medium was removed from the pelleted cells, and the tubes were inverted and rimmed with cotton swabs to ensure complete removal of all wash medium. Rabbit anti-cat IgG FITC conjugate was diluted to 1:20 in medium 199 and 0.05 ml was placed onto each FL-74 cell pellet. The cells were suspended in the conjugate and incubated for 30 minutes on ice.

NFL-74 cells were washed twice in medium 199, and each pellet was resuspended with one drop of 50% glycerol in PBS and placed on a slide. We read the test within 2 hours using a Zeiss fluorescent microscope.

TABLE 1.—*Test for FeLV antigens in human cells*

Malignant disease	Total No. of patients tested	No. of patients tested for:		No. of patients positive for FeLV antigens
		Normal leukocytes in peripheral blood	Tumor cells in peripheral blood	
Acute lymphocytic leukemia	43	43	35	0
Acute nonlymphocytic leukemia	38	38	31	0
Chronic leukemias	21	21	21	0
Lymphomas	40	40	22	0
Soft tissue sarcomas	49	49	0	0
Total	191	191	109	0

RESULTS

Antigen Studies

FeLV Antigens

A total of 191 patients were tested for FeLV antigens in their normal peripheral blood leukocytes or in tumor cells present in the peripheral blood (table 1). Of these, 49 patients had soft tissue sarcomas and 142 patients had hematologic cancers. All patients were negative for FeLV antigens in the cytoplasm of their peripheral blood normal leukocytes or of tumor cells in their peripheral blood. Two of the patients tested developed acute lymphocytic leukemia after having lived with cats who had died of FeLV-positive lymphosarcoma. In both patients, FeLV antigens were not found either in the leukemia cells at diagnosis or later in the normal peripheral blood leukocytes when the cancer was in remission.

FOCMA Absorption Tests

None of the 20 patients tested with hematologic tumors had FOCMA expressed on the cell membranes of tumor cells from their bone marrows (table 2).

Antibody Studies

SN Antibody to FeLV

We tested 239 patients for SN antibody against FeLV subgroups A and B. None of the 66 patients with soft tissue sarcomas and none of the 173 patients with hematologic cancers had SN antibody to FeLV at a titer of 1:2 or above (table 3).

TABLE 2.—*FOCMA absorption test on human cells*

Malignant disease	Total No. of patients tested	No. of patients with FOCMA-positive cells
Acute lymphocytic leukemia	6	0
Acute nonlymphocytic leukemia	10	0
Chronic leukemias	0	0
Lymphomas	4	0
Soft tissue sarcomas	0	0
Total	20	0

TABLE 3.—*Serologic tests of human cancer patients for SN antibody to FeLV and FOCMA antibody*

Malignant disease	SN antibody test against FeLV		FOCMA antibody test	
	No. of patients tested	No. of patients positive for SN antibody to FeLV	No. of patients tested	No. of patients positive for FOCMA antibody
Acute lymphocytic leukemia	49	0	6	0
Acute nonlymphocytic leukemia	46	0	7	0
Chronic leukemias	28	0	0	0
Lymphomas	50	0	4	0
Soft tissue sarcomas	66	0	3	0
Total	239	0	20	0

FOCMA Antibody

None of the 20 patients with hematologic cancers had antibody to FOCMA at a titer of 1:2 or above on FL-74 target cells (table 3).

Patients Exposed to FeLV-Positive Cats With Lymphosarcoma

Two patients with acute lymphocytic leukemia had lived with FeLV-positive cats with lymphosarcoma. Both patients were negative for SN antibody to FeLV and FOCMA antibody at the time of their diagnosis. In addition, both patients were still negative for these antibodies while in remission 12 months after diagnosis. We judge these findings significant considering that each patient developed the same type of neoplasia as did their FeLV-positive cats.

DISCUSSION

For the past 10 years, both epidemiologic and seroepidemiologic (immunologic) studies have been done to determine if humans exposed to cats or FeLV had an increased risk of developing cancer.

Several epidemiologic studies of veterinarians or of children and adults exposed to cats have been done with conflicting results. Veterinarians have a high occupational exposure to FeLV. Five mortality studies of a total of 23,249 U.S. veterinarians have been reported. In two of these studies of 876 veterinarians, no increase in the occurrence of any type of cancer was noted in veterinarians compared to the occurrence in the general public (*24*, *25*). In another study, skin melanomas were found in excess among veterinarians (*26*). However, two recent studies of many veterinarians have revealed a significant increase in the occurrence of lymphoid tumors. The first study reported an 80% increase in the mortality due to lymphoma among 19,000 veterinarians who died over the age of 45 years (*27*). The second study also showed a significant excess occurrence of leukemia and Hodgkin's disease among 1,551 male veterinarians in clinical practice (*28*). The authors of (*27*, *28*) were unable to prove a cause for the excess number of these tumors among veterinarians, although FeLV certainly must be considered.

Two retrospective studies of the exposure to cats of 328 children with leukemia have been done. A twofold increase in exposure to cats was found in houses in London where children developed lymphoid cancers compared to those where children developed other forms of cancer (*29*). Similarly, in a study performed in the United States of 300 children with leukemia and 831 control children, the relative risk among leukemic children exposed to "sick" cats was more than double that of the control children (*30*). In contrast, in retrospective studies of more than 1,965 adults exposed to cats, no increase in occurrence of cancer was found in individuals exposed to cats with lymphosarcoma or to healthy cats (*31–33*).

Seroepidemiologic or immunologic tests are more definitive methods of determining if FeLV can infect humans. These tests consist of immunologic procedures to determine if FeLV antigens exist in humans exposed to cats or if antibodies to FeLV or to FOCMA are produced by people exposed to infected cats. Eight studies to determine if antibody to FeLV occurred in a total of 4,069 people have been done and have yielded conflicting results. Four of the studies found antibody to FeLV antigens in 224 of 2,089 people (10.7%) (*34–37*). In four other studies, no antibody to FeLV was found in 1,538 healthy people, in 631 people with cancer, in 209 people with nonneoplastic diseases, or in 662 healthy veterinarians (*19*, *38–40*).

There have been only four studies that attempted to detect FeLV antigens in people. In one study, FeLV antigens were found in immune complexes in the glomeruli of 2 people with acute myelogenous leukemia (*41*). In another study, FeLV-related antigens were detected on the leukemia cell surface of 43 (81%) of 53 patients with myeloid leukemias and of 35 (97%) of 36 patients with lymphoid leukemia or lymphoma, but not on normal lymphocytes from 12 healthy people (*42*). No FeLV antigens were found in 439 people, of whom 4 had been bitten by FeLV-infected cats, 52 were veterinarians, 200 had lymphoid tumors, and 59 had carcinomas or sarcomas (*19*). Similarly, no soluble FeLV antigens were found in the sera of any of 1,324 people, 490 of whom had hematologic cancers (*40*).

Because 4 groups of investigators using various immunologic tests found antibody to FeLV (*34–37*), we attempted to confirm these observations on a larger series of human patients with soft tissue sarcomas or hematologic cancers. We chose to determine if FeLV was present in patients by the use of an indirect IFA test. A positive IFA test for FeLV in cats correlates with the ability to isolate FeLV from the plasma in 97.5% of cats studied (*18*, *43*). In addition, we used the FOCMA test on human cells to determine if FeLV or FeSV was involved in the induction of transformation of these cells, inasmuch as these viruses induce FOCMA in cat cells, which they transform (*20–22*). Most cats that are exposed to FeLV and then reject the virus and become immune produce both SN antibody to FeLV and FOCMA antibody (*19*). Therefore, as an indication of a history of FeLV or FeSV exposure, we chose to test human sera for these antibodies. Our study represents the most complete immunologic analysis of FeLV exposure in humans inasmuch as some of our patients had tests for FOCMA expression on the membranes of their tumor cells as well as tests for FeLV and for FeLV and FOCMA antibodies. This study is also significant because we were able to test 66 patients with soft tissue sarcoma, which is a relatively rare tumor in humans (comprising <1% of human malignant tumors) but is a type of tumor (multicentric fibrosarcoma) induced by the FeSV in pet cats.

In 191 human patients with various forms of cancer, we found no evidence of the presence of active FeLV replication in any of the patients. Nor did we find any evidence of *past* FeLV infection, as judged by the absence of FeLV SN antibody, in 239 human patients. Even the 2 patients with acute lymphocytic leukemia, who had lived in close contact in the same household with their FeLV-infected leukemic pet cats, were repeatedly negative for FeLV antigens and for SN antibody to FeLV. In addition, none of the 20 patients tested were positive for FOCMA antibody. We have not found any evidence of active FeLV infection or a history of past FeLV infection in any of the patients that we tested.

We must be cautious in the interpretation of these negative data, however, because 30% of the pet cats who developed lymphosarcoma as a result of known past exposure to the virus have neither FeLV antigens nor FeLV SN or FOCMA antibodies (*43-45*). However, we did not find FOCMA expression on the tumor cells from the bone marrows of 20 of these patients. This is the most reassuring evidence that FeLV or FeSV was not involved in the etiology of these tumors because FOCMA is expressed on the cell surface of all FeLV and FeSV-induced tumors of cats, as well as on experimentally induced tumors of other species (*21-23*).

Although we did not find evidence supporting a role for FeLV or FeSV as causative factors in human tumors, more studies are needed. Molecular biologic studies of the DNA of human tumors should be done for detection of either complete copies or fragments of FeLV or FeSV sequences (*46*). The etiology of FeLV-negative lymphosarcomas of pet cats may be the insertion of FeLV noncoding sequences called "long terminal repeats" (LTR), which may promote downstream expression of a cat oncogene (*47-48*). Similarly, a fragment of the FeLV genome (LTR) may integrate into human cells and induce transformation without expression of that sequence. Until definitive molecular biologic studies have been done, we recommend that FeLV-infected cats should not be kept as pets.

Interferon and Prostaglandins: Effects on Human Natural and Lectin-Induced Cytotoxicity[1]

Nicholas P. Lang,[2,3] **John R. Ortaldo,**[2,4] **Guy D. Bonnard,**[2] *and* **Ronald B. Herberman**[2]

ABSTRACT—Effects of interferons (IFN) and E-series prostaglandins (PGE) were evaluated on subpopulations of human peripheral blood mononuclear lymphocytes (PBL) that mediate natural killer (NK) activity, antibody-dependent cell-mediated cytotoxicity (ADCC), or lectin-induced cellular cytotoxicity (LICC). When PBL were separated into subpopulations depending on the presence or absence of receptors for sheep erythrocytes (E^+ or E^-, respectively) or for the Fcγ receptor ($Fc\gamma R^+$ or $Fc\gamma R^-$, respectively), LICC was mainly associated with the $E^+Fc\gamma R^-$ cells and to a considerably lesser extent with $E^+Fc\gamma R^+$ cells. In contrast, NK activity and ADCC were associated with the E^+ and E^- subpopulations that had FcγR. IFN treatment had stronger effects on the $Fc\gamma R^+$ subpopulations. Boosting of LICC occurred maximally in the $E^+Fc\gamma R^+$ subpopulation, and the activity of the $E^+Fc\gamma R^-$ cells increased only modestly. IFN had a greater augmenting effect on the NK activity and ADCC of $E^+Fc\gamma R^+$ cells than on $E^-Fc\gamma R^+$ cells. PGE strongly inhibited all three types of cell-mediated cytotoxicity and was effective on IFN-boosted cells as well as on untreated cells.—JNCI 1982; 69:339–343.

Recent data from this laboratory (*1*, *2*) and from other laboratories have indicated that IFN is an important mediator of activation or boosting of human and rodent NK and ADCC cells. Additional evidence that IFN can boost cytotoxic reactivity of human and rodent monocytes (*3–5*) indicates that IFN is involved in the positive regulation of a variety of cytotoxic effector cells. Although addition of IFN to human mixed lymphocyte cultures resulted in the development of higher levels of cytotoxicity, short-term IFN treatment did not boost the activity of the CTL after they were generated (*6*).

The apparently divergent effects of IFN on NK cells and CTL raised the possibility that only certain types of cytotoxic effector cells or subpopulations of lymphoid cells are responsive to augmentation by IFN. In vitro generated human CTL are found exclusively in subpopulations of T-cells forming rosettes with E and lacking detectable FcγR (i.e., $E^+Fc\gamma R^-$ cells), whereas NK activity and ADCC have been associated only with $Fc\gamma R^+$ cells, both E^+ and E^-. The cells mediating cytotoxicity in the presence of the lectin PHA have been found to have similar surface characteristics as in vitro generated CTL (*7*, *8*). In the present study, we have examined the effects of IFN on NK activity, ADCC, and LICC of various subpopulations of PBL.

It has also been of interest to determine the factors involved in negative regulation of cell-mediated cytotoxicity and other immune functions. PGE appear to play an important role, possibly exerting their effect by stimulating adenyl cyclase and thereby causing an intracellular increase in cAMP (*9*). PGE has been shown to suppress blastogenesis, to inhibit leukocyte inhibitory factor production (*10*), to increase granulocyte migration (*11*), to boost IFN-induced suppression of antibody production (*12*), and to suppress ADCC (*5*) and NK activity in rodents (*13*). CTL activity (*14*, *15*) and activated macrophage cytolysis in rodents (*16*) are also suppressed by PGE. PGE also could suppress IFN production by mitogen-stimulated human PBL (*17*). As with IFN, there are indications for some selectivity of the effects of PGE on various lymphoid cell subpopulations. PGE did not affect the activity of resting macrophages (*16*). Furthermore, others (*18*) have shown that PGE could inhibit the lymphoproliferative responses of one subpopulation of T-cells but actually augment the reactivity of another subpopulation.

It was therefore of interest to determine the effects of PGE on various human effector cell activities and subpopulations and to determine whether cells activated by IFN were as sensitive to inhibition as were unstimulated cells.

MATERIALS AND METHODS

Culture medium.—RPMI-1640 tissue culture medium (Biofluids Inc., Rockville, Md.), buffered with 10 m*M* HEPES[5] (M.A. Bioproducts, Walkersville, Md.), was used for all cell cultures and cytotoxicity assays. The medium was supplemented with 1 m*M* glutamine (National Institutes of Health Media Unit), 55 μg gentamicin reagent solution/ml (Schering Corp., Kenilworth, N.J.), and 10% FBS (Grand Island Biological Co., Grand Island, N.Y.). FBS was routinely heat inactivated and filtered through a 0.22-μm micropore filter before use in tissue culture medium.

IFN treatment.—PBL ($1\text{-}5\times10^6$/ml) were incubated in RPMI-1640 medium containing 10% FBS at 37°C for specified times, with or without IFN (1,000 U/ml) (HEM Re-

[5] 4(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

search Inc., Rockville, Md.). This IFN is type β, induced in human fibroblasts by polyinosinic-polycytidylic acid, and purified by hydrophobic affinity chromatography to approximately 3×10^7 U/mg. Unless specified, lymphocytes were washed with complete medium before treatment or testing.

Effector cells.—Mononulear cells were isolated from heparinized peripheral blood of healthy normal volunteers by centrifugation on Ficoll-Hypaque. Whole blood was diluted 1:1 (vol/vol) with phosphate-buffered 0.83% NaCl solution and then overlaid on a Ficoll-Hypaque solution (lymphocyte-separating medium; Litton Bionetics Inc., Kensington, Md.). The blood was centrifuged at 450×*g* for 30 minutes as previously described (*19*) or at 900×*g* for 8 minutes. Cells were recovered from the interface, washed twice with Hanks' balanced salt solution without serum, and adjusted to appropriate concentrations for use.

Cell separation techniques—Spontaneous sheep rosette PBL were mixed with sheep E, rosettes were allowed to form spontaneously at 4°C, and E$^+$ and E$^-$ cells were separated by centrifugation on Ficoll-Hypaque. The red blood cells in the pellet containing E$^+$ cells were lysed by addition of 3 ml of distilled H_2O to the pellet followed in 15 seconds by 25 ml of FBS for prevention of lymphocyte damage. This population contained greater than 98% E$^+$ cells, as measured by the 4°C sheep E-rosette assay. The E$^-$ fraction contained 2-3% E$^+$ contaminating cells by the same assay.

FcγR separation.—The E$^+$ and E$^-$ fractions were then further separated into FcγR$^+$ and FcγR$^-$ cells by two methods. The first method (*19*) involved separation by FcγR$^+$ depletion on an antigen-antibody monolayer. We removed the FcγR$^+$ cells (which adhered to the monolayer) by rinsing the monolayer with 0.01% EDTA in phosphate-buffered 0.83% NaCl solution and by scraping cells with a rubber policeman. Before being tested, the subpopulations of cells were incubated overnight at 37°C in 5% CO_2. Recovery after the procedure ranged from 60 to 85% with more than 90% viability at the time of testing.

The second method involved separation with the use of bovine E and IgG anti-bovine EA (Cappel Laboratories, Inc., Thurd Ridge Farm, Cochranville, Pa.). The procedure was a slight modification of the technique reported by Shaw et al. (*20*). EA$^+$ and EA$^-$ cells were incubated with bovine E coated with IgG (EA-IgG) at 4°C for 1 hour. The cells were then separated on a Ficoll-Hypaque gradient. The pelleted cells were termed "FcγR$^+$," and the interface cells were termed "FcγR$^-$." Adherent E were lysed with H_2O as described above. The lymphocytes were then cultured overnight at 37°C in 5% CO_2 as above before they were tested. The purity of each fraction was evaluated with the use of E-rosettes and EA rosettes. The E$^+$FcγR$^+$ fraction contained 3% FcγR$^-$ cells, and the E$^+$FcγR$^-$ fraction had less than 1% FcγR$^+$ cells. The E$^-$FcγR$^+$ fraction had an average of 10% FcγR$^-$ contamination, whereas the E$^-$FcγR$^-$ fraction had an average of 7% FcγR$^+$ cells.

Culture conditions.—A total of 5-10^7 lymphocytes in 1-2 ml of complete medium was added to 17×100-mm plastic tubes (#2057; Falcon Plastics, Oxnard, Calif.) and incubated overnight at 37°C in a 5% CO_2 atmosphere. At the end of the culture, the lymphocytes were washed, adjusted to the desired concentrations, and tested for cytotoxicity.

Target cells.—The human myeloid cell line K562 (*21*) was used as a target cell for the detection of natural cytotoxicity as previously described (*19*).

Chang liver cells (*22*) were used as target cells in the LICC and ADCC assays. The Chang cells used in the ADCC assay were sensitized with a 1/50,000 dilution of rabbit anti-Chang antisera (*19*). DNase (Sigma Chemical Co., St. Louis, Mo.) at a final concentration of 0.1 μg/ml was added to Chang cells during ^{51}Cr labeling for prevention of clumping.

CRA.—The CRA for NK activity (and ADCC and LICC where indicated) was slightly modified from that which we described earlier (*19*). Target cells ($\approx 2\times10^6$ in 0.5 ml medium containing 10% FBS) were labeled by incubation with 0.15 ml (200 μCi) of ^{51}Cr as sodium chromate (New England Nuclear Corp., Boston, Mass.) for 45 minutes at 37°C, washed twice in 50 ml of medium, and resuspended at 1×10^5 cells/ml. The 5×10^3 ^{51}Cr-labeled cells in 0.05 ml were added to 0.05 ml of varying concentrations of effector lymphocytes, ranging from 100:1 to 1:1 E:T ratios in medium in 0.2-ml wells of a 96-well Linbro plate (catalogue #76-311-05; Flow Laboratories, Inc., Rockville, Md.). The plates were incubated for 4 hours at 37°C in a 5% CO_2 humidified incubator. The supernatants were harvested by means of a Titertek harvester (Flow Laboratories), and their ^{51}Cr content was measured in a Biogamma II counter (Beckman Instruments, Fullerton, Calif.). All test combinations were performed in triplicate. Both an autologous control and a medium control were included in all assays and consisted of unlabeled target cells or medium alone, respectively, added in place of (and at the same concentration as) effector lymphocytes. These controls provided the measurement of base-line release of ^{51}Cr from target cells under the conditions of both high cell densities (as was encountered at high E:T ratios) or in medium alone, which usually ranged from 5 to 12% of the total label incorporated.

The percentage of specific ^{51}Cr release was calculated as $(A-B)/T\times100$, where A=mean cpm of test samples; B=mean cpm of autologous control; and T=mean cpm of the total amount of ^{51}Cr incorporated into the target cells at the time of labeling; background cpm of the gamma counter were first subtracted from each of these parameters (*19*). This calculation, which does not subtract spontaneous release from the denominator, gives somewhat lower percentages of cytotoxicity than those reported by other investigators, as has been discussed by Herberman et al. (*23*).

LICC.—This assay was performed by addition of PHA (H-16; Burroughs Wellcome Co., Research Triangle Park, N.C.) as the lectin, at specified final concentrations, to the 4-hour CRA. ^{51}Cr-labeled Chang cells were used as the target at 5×10^3 cells/well as in the CRA and ADCC assay.

Calculation of LU.—As previously described (*19*), we obtained dose-response curves by plotting the percentages of specific ^{51}Cr release obtained at each of several E:T ratios. An LU was then defined as that number of effector cells, extrapolated from the dose-response curve, required to achieve 30% specific target cell lysis. To more easily compare the lytic capacity of different cell populations which may have differed in cell yield or recovery, we frequently expressed the data as LU/10^7 effector cells.

Treatment with PG or cyclic nucleotides.—PGA$_1$, PGA$_2$, PGB$_1$, PGB$_2$, PGE$_1$, PGE$_2$, PGF$_{1\alpha}$, PGF$_{2\alpha}$, and cyclic nucleotides (db-cAMP and db-cGMP) (Sigma Chemical Co.) were dissolved in 95% ethanol as stock solutions and stored at −70°C. The reagents used in experiments were then prepared as 1/100 to 1/10,000 (vol/vol) dilutions of stock solutions with the use of RPMI-1640. Controls with the use of 1/100 dilutions of 95% ethanol showed no change from medium controls. Concentrations of each reagent are indicated in the tables.

RESULTS

Pretreatment of PBL with IFN resulted in substantial augmentation of LICC as well as NK activity and ADCC. To look for possible heterogeneous effects on subpopulations of cells, we made separations according to the presence or absence of receptors for E and of FcγR.

Table 1 shows the results of four experiments with subpopulations of PBL when tested for LICC and NK activity, with or without IFN augmentation. No significant activity (5% cytotoxicity at 50/1) was seen against Chang targets in the 4-hour CRA; however, addition of PHA efficiently elicited LICC. As previously reported (*8*), most LICC was associated with the $E^+FC\gamma R^-$ fraction, and LICC was significantly increased by IFN. The $E^+Fc\gamma R^+$ cells had very low LICC, but LICC was markedly increased after IFN treatment. Significant NK activity and boosting were seen only with $Fc\gamma R^+$ populations. Whereas higher spontaneous activity was seen in the $E^-Fc\gamma R^+$ cells, IFN caused relatively more augmentation of activity of the $E^+Fc\gamma R^+$ cells. The large boost in LICC seen with the $E^+Fc\gamma R^+$ cells was not due to NK activity, since IFN-treated effectors gave only a mean of 7 LU (data not shown) on Chang cells in the absence of PHA, compared to the 112 LU with lectin addition. Recovery of lytic activity (*see* footnote, table 1) demonstrated that manipulation on populations did not account for these results.

Table 2 shows the effects of PG addition to NK and K-cell assays. PGE and $PGF_{2\alpha}$ were the only consistent inhibitors of cytotoxic activity. Preincubation of effectors for 30 minutes and then removal of PG had no significant effect on NK or K-cell activity, demonstrating the rapid reversibility of these agents. As can be seen, PGE_1 and PGE_2 significantly depressed NK and K-cell activities and also LICC. The $PGF_{2\alpha}$ depression shown in table 2 was not consistent in repeat experiments, and $PGF_{1\alpha}$ had minimal inhibitory effects and often enhanced cytolysis. PGA_1, PGA_2, PGB_1, and PGB_2 had no effects on the results (data not shown). Since PG are known to result in changes in cyclic nucleotides, db-cAMP and db-cGMP were also tested. As expected, cAMP (only when present during the assay) and not cGMP inhibited NK and K-cell killing and also LICC.

TABLE 1.—*Effect of IFN on lymphoid subpopulations mediating NK activity and LICC*

Subpopulation	IFN	Cytotoxicity, LU/10^7 cells[a]			
		LICC		NK activity	
		Mean	Range	Mean	Range
$E^+Fc\gamma R^+$	−	2.95	1.4–4	54.6	3.4–117
	+	112	28–224	252	43–662
$E+Fc\gamma R^-$	−	20.3	3.8–38	0	—
	+	83.7	32–135	2	0–6
$E^-Fc\gamma R^+$	−	0.17	0–0.5	110	3–309
	+	4.2	0–11.2	235	9.6–486
$E^-Fc\gamma R^-$	−	0	—	0	—
	+	6.5	0.9–12	4.2	0.1–8.4

[a] For LICC, mean unseparated PBL activity prior to separation was 30.8 LU without IFN (75% recovery) and 267 LU with IFN (77% recovery); for NK activity, it was 181 LU without IFN (91% recovery) and 404 LU with IFN (122% recovery).

TABLE 2.—*Effect of PG and cyclic nucleotides when present in assay for 4 hours*

Agent added to assay (concentration, *M*)	Cytotoxicity activity, LU/10^7 cells		
	NK	LICC[a]	ADCC
Medium	225	87	46.7
PGE_1 (10^{-5})	29.8	12	3.0
PGE_2 (10^{-6})	20.0	7	14.7
$PGF_{1\alpha}$ (10^{-5})	171	NT	79.3
$PGF_{2\alpha}$ (10^{-6})	87.4	NT	15.1
cAMP (10^{-3})	12.0	5	7.0
cGMP (10^{-3})	194	91	72.6

[a] NT=not tested.

TABLE 3.—*Effects of cAMP on spontaneous and IFN-boosted NK activity*[a]

Treatment	Concentration, *M*	Cytotoxic activity			
		Without IFN		With IFN	
		LU/10^7 cells	Percent control	LU/10^7 cells	Percent control
Medium	—	147	—	226	—
cAMP	10^{-3}	7	5	75	33
cAMP	10^{-5}	107	72	144	77
cAMP	10^{-7}	209	142	219	97
cAMP	10^{-9}	219	148	244	107

[a] Results with cGMP (doses of 10^{-3}–10^{-9} *M*) showed no significant depression of NK activity, and data are not shown.

Since IFN and PGE had opposite effects on NK activity and since PG seemed to act through changes in cyclic nucleotides, it was of interest to determine how cAMP would affect IFN-augmented NK cells. As shown in table 3, a similar dose-dependent inhibition of both spontaneous and IFN-augmented NK activity was seen with cAMP. However, in contrast to spontaneous activity, the activity of boosted cells could never be completely inhibited, which suggests some resistance to negative regulation by the IFN-activated cells.

DISCUSSION

IFN has been shown here to have quantitatively different effects on various subpopulations of PBL. These observations are compatible with the previous observations that IFN did not augment the cytotoxicity by CTL against allogeneic blasts (*6*). It remains possible that long-term exposure of cells to IFN in mixed lymphocyte reaction might render them less sensitive or insensitive to augmentation. However, the $E^+Fc\gamma R^-$ cells involved in LICC show the same cell surface marker characteristics as CTL (*24*) and were augmented significantly by IFN (with short exposure), but not to the marked extent seen with $E^+Fc\gamma R^+$ cells. The $E^+Fc\gamma R^+$ cells accounted for most (60–80%) of the IFN-induced augmentation in NK and LICC reactivities. $E^-Fc\gamma R^+$ or $E^-Fc\gamma R^-$ cells appeared to lack the ability to mediate LICC, even after treatment with IFN.

Our results show that IFN is capable of augmenting both NK activity and LICC. The differential effect of IFN on E^+ and E^- populations could be explained by either a decrease in the number of cells present in the E population that are sensitive to IFN stimulation or a decrease in the sensitivity of all cells in the population to stimulation by IFN. This is consistent with the point previously made (*7*) that LICC effector cells and NK cells are differently distributed between E^+ and E^- cells, and it indicates that only cells with the inherent ability to moderate a particular effector function can be activated to do so by IFN.

Another interesting finding in this study is the tendency of $Fc\gamma R^+$ cell populations to be more susceptible to boosting by IFN. This feature was observed with the subpopulations involved in LICC and NK functions in addition to monocyte and polymorphonuclear leukocytes. This finding is particularly interesting because there is little evidence that the FcγR is directly involved in LICC or NK activity. The FcγR may simply make a cell population that is particularly receptive to boosting by IFN.

The data concerning the effects of PG on ADCC support work previously reported (*25*). In addition to confirming this study, we have also shown that PG could affect the cytolytic function of human NK cells and of LICC. Previous reports suggested that PGE has its effect on lymphocytes by stimulating adenyl cyclase to produce an increase in intracellular cAMP (*26*). Our data show similar effects by these two agents and would support these conclusions. These two agents appear to be capable of inhibiting a wide array of cytolytic activities. These cytolytic activities may have final common pathway that is being blocked by PGE_1 and db-cAMP.

Although data available at this time suggest that IFN and PGE have opposite effects on cytolysis, there is no evidence that these compounds have any influence at the same step in the cytolytic pathway. PGE was capable of depressing cytolytic function of IFN-boosted human PBL, but to get the same degree of suppression required increased levels of PGE (data not shown). The suppression by PGE was not absolute following stimulation by IFN; the PGE treatment caused suppression of cytotoxic activity to levels below those of unstimulated PBL but not to the levels of depression seen in PBL treated with PGE alone. The temporal sequences required for the IFN and PGE effects were different. IFN pretreatment, even for a very short time (5 min), still produced a sustained effect on cytotoxicity, which suggests that IFN acts as a trigger for the production of relatively long-lived products. PGE, however, seems to produce its inhibitory effects through a much more evanescent product. A recent report has indicated that more prolonged pretreatment of human PBL with PGE may lead to stimulation of NK activity (*27*), which points out the possible complex and pleiotropic effects of PG.

It is very important to understand both the positive and negative regulatory facts on cytolytic effector cells. Increased knowledge in the area might lead to rational protocols for in vivo manipulation of the levels of cytolytic effector activities. Immune adjuvants may act largely via their ability to induce IFN and thereby activate or augment the activity of cytolytic cells. Conversely, elimination or reduction of PGE production might overcome inhibition of cytotoxic activity. In vivo data in mice from our laboratory and from other laboratories (*28*) have demonstrated decreased tumor growth in indomethacin-treated mice, which supports this hypothesis.

Indirect Macrophage Migration Inhibition Response to 3-*M* KCl Extract of Gastric Carcinoma[1]

Tsuyoshi Akiyoshi,[2] Fumio Koba,[2] Michihiro Kawaguchi,[2] Soichiro Miyazaki,[2] *and* **Hideo Tsuji**[2]

ABSTRACT—With the use of indirect macrophage migration inhibition (MMI) test, the MMI response to 3-*M* KCl extract from gastric carcinoma or adjacent normal tissue was studied in patients with gastric carcinoma, in patients with other types of carcinoma, and in normal controls. The migration index (MI) of less than 75, which was 2 SD below the mean MI of normal controls, was considered positive. Twelve (23%) of 52 patients with gastric carcinoma showed positive response to autologous tumor extract, whereas only 2 (6%) of 35 patients responded to autologous normal tissue extract ($P<0.03$). Positive response to allogeneic gastric carcinoma extract occurred in 4 (9%) of 47 patients with gastric carcinoma and in none of 25 patients with other types of carcinoma. None of 39 patients with gastric carcinoma and 19 patients with nongastric carcinoma responded to allogeneic normal tissue extract. These results appeared to show a lower degree of sensitivity but a relatively higher degree of specificity in the indirect MMI test, as compared to those in the direct leukocyte migration inhibition test, for detection of the cell-mediated immune response to tumor-associated antigens in patients with gastric carcinoma.—JNCI 1982; 69:345–347.

The MMI test has proved to be a sensitive in vitro method for detection of cellular immune response to purified antigens in experimental animals and has been modified for use in clinical studies, whereas the LMI test has been monitored. The direct LMI assay is now widely accepted as a means of examining cell-mediated immunity against human neoplasms, and it has revealed discrimination in reactivity between healthy donors and patients with various malignant tumors (*1–9*). As for gastric carcinoma, however, few results have been reported (*10*).

Conversely, the indirect MMI test (*11*) has been scarcely utilized for detection of cell-mediated immunity in patients with malignant tumors (*12–14*), although it has been used as an in vitro method in the detection of cellular immune response to purified antigens in humans. The indirect MMI technique as well as the indirect LMI test (*15, 16*) could decrease the possibility of false-positive migration inhibition reactions that might occur in the direct LMI test as a result of toxicity of antigen preparation on leukocytes.

Using the indirect MMI test in the present study, we examined the cell-mediated immune response to autologous 3-*M* KCl extract of tumor or adjacent normal tissue in patients with gastric carcinoma. These responses were compared with those produced by patients with gastric carcinoma to allogeneic extract, by patients with other types of carcinoma, and by normal control subjects.

MATERIALS AND METHODS

Patients.—Heparinized whole blood was obtained from 86 patients with gastric carcinoma and from 31 patients with the other types of carcinoma. Patients were tested before the operation or in the postoperative period (7–21 days) prior to chemotherapy, radiotherapy, and/or immunotherapy. Blood specimens were also obtained from 42 normal controls.

Extracts.—Extracts of tumor (3 *M* KCl) and adjacent normal tissue were prepared by modifications of the method described by Meltzer et al. (*17*). Tissue samples were dissected from surgical specimens under sterile condition and minced finely with a scalpel. Minced tissue was suspended in cold 3-*M* KCl solution at pH 7.3 and incubated at 4°C for 16–24 hours. The mixture was then centrifuged at 40,000×*g* for 60 minutes at 4°C. The supernatant was desalted twice against 200-volume distilled water for 1 hour. The desalted supernatant was centrifuged at 40,000×*g* for 15 minutes and dialyzed against 200-volume phosphate-buffered saline for 1 hour. The dialyzed extract was sterilized by Millipore membrane filtration, and protein concentration was determined by Lowry's method (*18*). Samples of each extract were stored at −80°C.

Indirect MMI assay.—The method described by Rocklin and David (*11*) was used with minor modifications. Mononuclear cells from heparinized peripheral blood, prepared by Ficoll-Conray separation, were suspended in medium 199 supplemented with 100 U penicillin/ml and 100 µg streptomycin/ml to a concentration of 3×10^6 cells/ml for culture. A concentration of 250 µg 3-*M*-KCl extract/ml was added to the cells, and mononuclear cell cultures were then incubated at 37°C in a humidified 5% CO_2 atmosphere for 3 days. The cell-free supernatants were carefully removed each day and, medium with and without the original extracts was replaced to maintain the original volume. The collected supernatants were dialyzed in cold against 0.9% NaCl, redialyzed against distilled water, and concentrated by lyophilization. The lyophilized supernatants were resuspended in medium 199 containing 10% guinea pig serum and 5% fetal calf serum at one-third of the original volume, sterilized by Millipore membrane filtration, and adjusted to pH 7.4 with CO_2 in air. Controls consisted of the cell-free supernatant from similar mononuclear cell culture incubated without extract; the extract was added after the total collection.

To measure the macrophage migration inhibitory factor activity in these supernatants, we utilized modifications of

[1] Received July 30, 1981; revised December 27, 1981; accepted February 17, 1982

[2] Department of Surgery, Research Institute of Balneotherapeutics, Kyushu University, Beppu 874 Japan.

the capillary migration technique of Rocklin and David (*11*). Capillary tubes were filled with the cell suspension of peritoneal exudate cells from normal guinea pig and centrifuged. The tubes were cut, and the portion containing the cells was placed in Mackaness-type chambers, two capillaries per chamber. The chambers were filled with the media to be assayed and incubated at 37°C for 24 hours. Then the area of migration of cells from capillary tubes was projected and measured by planimetry, and percentage migration (MI) was calculated from the following formula: Migration index = (average area of test supernatant/average area of control supernatant) × 100. The average area was calculated with at least six capillary tubes.

RESULTS

A total of 307 indirect MMI tests were performed on 86 patients with gastric carcinoma, 31 patients with nongastric carcinoma, and 42 normal controls. All individuals were tested with 3-*M* KCl extracts derived from gastric carcinoma or adjacent normal tissue. The results obtained from normal control subjects were shown in text-figure 1. The mean MI were 103.1±13.0 with tumor extract and 100.9±13.9 with normal tissue extracts, respectively. Therefore, the limit for a positive assay was set at 75, which was 2 SD below the mean (102.1±13.4) of normal controls tested with both tumor and normal tissue extract.

For evaluation of the accuracy of the indirect MMI assay, we divided the cells from the same patient and tested duplicate specimens simultaneously and separately for the MMI response to autologous tumor extract. As shown in table 1 MI values rarely differed more than 20, and frequently the difference was less than 10.

Text-figure 2.—Indirect MMI responses of patients with gastric carcinoma and other types of carcinoma to 3-*M* KCl extract of gastric carcinoma and adjacent normal tissue.

As shown in text-figure 2, a positive MMI response to autologous tumor extract was found in 12 (23%) of 52 patients with gastric carcinoma. In contrast, only 2 (6%) of 35 patients with gastric carcinoma showed positive response against autologous normal tissue extract. The difference was statistically significant ($P<0.03$; Fisher's exact probability test). The MMI response to extract derived from allogeneic gastric tissue was measured in 47 patients with tumor extract and in 39 patients with normal tissue extract. Four (9%) of 47 patients responded to extract of allogeneic gastric cancer tissue, whereas none of 39 patients responded to the extract of allogeneic adjacent normal tissue. None of the patients with other types of carcinoma responded to the extract of gastric carcinoma (25 tested) or adjacent normal tissue (19 tested).

DISCUSSION

In this study we have measured the indirect MMI response of gastric carcinoma patients to 3-*M* KCl extract derived from gastric carcinoma or adjacent normal tissue. We have additionally evaluated the MMI response in patients with nongastric carcinomas to 3-*M* KCl extract of normal and cancerous gastric tissue.

Our response rate to autologous tumor extract was 23%, and it was significantly different from that to autologous normal tissue extract. However, the rate was relatively lower than that reported by other investigators which was obtained with the use of the direct LMI test in patients with various carcinomas (*2*, *7*, *9*). It may be partially related to the timing of the tests relative to surgery because our tests were performed in the postoperative period (7–21 days), which is a time of immune suppression as reported by several authors (*19*, *20*).

The results of this study similarly showed low frequency of positive response in patients with gastric carcinoma to allogeneic tumor extract compared to the LMI response to various carcinomas reported by other investigators (*1–6*, *8–10*), although none of 39 patients showed positive response to allogeneic normal tissue extract. With the use of the direct LMI test, Zöller et al. (*10*) found that 39 (91%) of 43 patients with gastric carcinoma, compared to 5% of patients with nonmalignant diseases and 3% of normal controls, responded to a panel of allogeneic 3-*M* KCl tumor extracts, whereas patients with nongastric carcinoma were sensitized in 36% (49/135) of the cases.

In the present study we utilized the indirect MMI test in which inhibition was not due to toxicity of tumor extract as it might be seen in the direct LMI test (*21*). In this system, involvement of histocompatibility antigens was unlikely because none of these patients with carcinoma showed positive response to allogeneic normal tissue extract. Furthermore, the present results showed the lack of reactivity in patients with gastric carcinoma to allogeneic normal gastric tissue extract. Thus the indirect MMI reactivity might be largely directed against tumor-associated antigens of gastric carcinoma. Our lower response rates to autologous or allogeneic tumor extract appeared to be related to the reasons described above.

Of 81 autologous tests 5 were associated with an MI greater than 129, which might suggest enhancement of migration (*22*). This enhancement also occurred in those in the presence of allogeneic tissue extract (8 of 130 tests). The significance of this phenomenon remains to be determined.

The results of the present study suggested that the indirect MMI test appeared to have a lower degree of sensitivity but a relatively higher degree of specificity, as compared to the direct LMI test, for detection of cell-mediated immune response to tumor-associated antigens in patients with gastric carcinoma. To determine the significance of the test in comparison with direct or indirect LMI assay, further studies with this test in patients with other types of carcinoma are presently under way.

Ten- to Fourteen-Year Effect of Screening on Breast Cancer Mortality[1, 2]

Sam Shapiro, *B.S.*,[3] **Wanda Venet**, *B.S., R.N.*,[4] **Philip Strax**, *M.D.*,[5]

ABSTRACT—Results from the randomized trial conducted by the Health Insurance Plan (HIP) to determine the efficacy of breast cancer screening with mammography and palpation are reported for longer periods than previously available. By the end of 10 years after entry, the study group's mortality due to breast cancer was about 30% below the control group's. Arithmetic gains due to screening were maintained through year 14; relative gains declined. With increases in the period of follow-up, cumulative survival rates among cases detected by mammography alone (palpation negative during screening), decreased more rapidly than rates among other subgroups, but survival rates for mammography cases remained relatively high. Study women aged 40–49 years at entry began to show lower breast cancer mortality than those in the control group as duration of follow-up increased. Reservations are advanced about the acceptance of this finding as evidence of the efficacy of screening under age 50 under the conditions of the HIP study. The reservations are based on the observation that the decrease of mortality among the study group aged 45–49 at entry is concentrated entirely among cases diagnosed after they reached 50 years of age.—JNCI 1982; 69:349–355.

The favorable impact of periodic screening with mammography and clinical examination of the breast on mortality from breast cancer shown by the HIP Study has been extensively reported for the short-term period of 5 years after the start of screening and for several subsequent years (*1*). Stimulated by these results, a number of issues have attracted attention that affect the spread of large-scale screening programs, e.g., the independent contribution of mammography (*2*), the age groups that benefit from screening, the radiogenic effect of mammography, and the risk-benefit effects of screening at various intervals (*3–5*). At the same time, it has been well recognized that the efficacy of screening will not be adequately comprehended until we know the long-term effects on mortality.

Short- to intermediate-term reduction in mortality is close to one-third, but the absence of information on the natural history of breast cancer detected through screening leaves uncertain whether this reduction represents a cure or a postponement in mortality from breast cancer. Evidence on this issue would have great significance not only for screening but also for the more general understanding of the biology of breast cancer. At this point, the data on breast cancer detected in clinical practice show that even among cases diagnosed at a localized stage, there continues to be excess mortality for long periods after diagnosis (*6*).

The discussion that follows represents a start in addressing the question of long-term effects related to screening through an extension of previously reported observations into a 12- to 14-year period of follow-up.

METHODS

Population source and observation methods.—To test the efficacy of periodic screening with mammography and clinical examination, we selected two systematic random samples, each consisting of about 31,000 women aged 40–64 years, from members of HIP, a comprehensive, prepaid group practice. Study women were offered screening examinations; the 65% who appeared for an initial examination were offered three additional examinations at annual intervals unless earlier follow-up or biopsy was indicated. All but a small proportion (12%) had at least one additional annual examination. Screening consisted of a clinical examination, usually by a surgeon; mammography, in which two views were taken of the breast (cephalocaudad and lateral); and an interview to obtain relevant demographic information and a health history. Independence between the two examining modalities was strictly maintained. Initial screenings began in December 1963 and continued through June 1966; annual rescreenings ended in June 1970. Control women continued to receive their usual medical care. The extent to which women in the study and control groups had general physical examinations (including breast examinations) or engaged in breast self-examination after the completion of the screening project is not known. At HIP, mammography was utilized extensively for differential diagnostic purposes but not as part of a program for early detection among asymptomatic women.

Follow-up procedures.—All observations relate to women in the study and to control groups with no breast cancer diagnosed prior to their entry into the study. Follow-up procedures for identification of breast cancers and deaths due to breast cancer or other causes have been applied equally to the study and control groups. These include periodic communication with women (or their next of kin) on the breast cancer registries established in the study, searches of hospital insurance and death records, and surveys

5 and 10 years after entry of all 62,000 women whose status was not already known through other sources. Other tracing methods are being applied for residual groups, and a new survey 15–17 years after entry is under way. Results thus far indicate that nearly all cases of breast cancer that occurred during the first 10 years after entry are now known; however, this may not be so for later years. Accordingly, mortality due to breast cancer, the primary measure for determining efficacy of screening, is restricted to cases detected in the 10-year interval. The end point for detection of breast cancer deaths among these cases is 14 years from entry; all study and control group women were observed for this period of time, and survival status of all cases on the breast cancer register has been ascertained.

Also presented are case survival rates among women with breast cancer histologically confirmed during the first 5 years after entry. The secondary position given to these rates in the determination of efficacy of screening results from *a*) the lead time in detection gained by the cases detected through screening and from *b*) the tendency of screening to select individuals with longer mean duration of preclinical disease. (In these instances each subsequent stage of disease may be more indolent, giving rise to a bias termed "length-biased sampling" (*7–9*), the effect of which diminishes as new cases are accrued.)

Life-table methods have been applied with the use of 6-month intervals after diagnosis. All breast cancer cases had a minimum of 9.5 years of exposure by December 31, 1980, the cut-off date for this report. The maximum period for which survival rates are given is 12 years[8] after which the numbers of cases withdrawn due to incomplete exposure become relatively large. Recalculation of survival rates between 9.5 and 12 years with the use of 1-month intervals shows that the resulting cumulative survival rates differ from the rates based on 6-month calculations by less than 1%.

Comparability of study and control groups.—High levels of comparability between the study and control groups have been demonstrated for a wide range of demographic and other characteristics (*10*) and for general mortality other than breast cancer (table 1). There are, however, large differences in general mortality between the study women who participated in the screening program and those who refused. The differential appears to be decreasing as the interval from entry increases, but the margin is still large (28%)—6–10 years from entry. This evidence of bias in the self-selection for screening has emphasized the importance of comparisons based on the total study group (screenees and refusers combined).

RESULTS

Breast Cancer Detection

Case detection information has been described elsewhere in detail (*1*); only a few of the results will be given here. By the end of 5 years from entry, which covers about 1.5 years after the last screening cycle, the gap between the breast cancer rates of the total study and control groups had become small (2.03 and 1.94/1,000 person-yr, respectively). Women who refused screening had a low rate of breast cancer (1.58/1,000) as compared with the rate among controls, indicating that women with a higher risk for breast cancer tended to self-select themselves for screening. Clinical and mammography examinations both contributed cases not detected by the other; the relative contribution of mammography (in the absence of clinical findings) was less among women under 50 years of age at diagnosis than among those 50 and over (14.4 vs. 37.6%). The proportion with no histologic evidence of axillary nodal involvement was higher among study cases than in the control group (56.4 vs. 46.3%). Breast cancers detected through screening had an especially high proportion with no nodal involvement (70.5%).

TABLE 1.—*Mortality from all causes excluding breast cancer: 10-year follow-up after entry*[a]

Population	Mortality at following intervals from entry:		
	10 yr	1–5 yr	6–10 yr
Total study	65.5	54.9	76.7
Screened	54.9	42.3	68.1
Refused screening	87.2	80.4	94.3
Control	64.8	56.5	73.4

[a] Rates per 10,000 person-yr.

Mortality Differentials

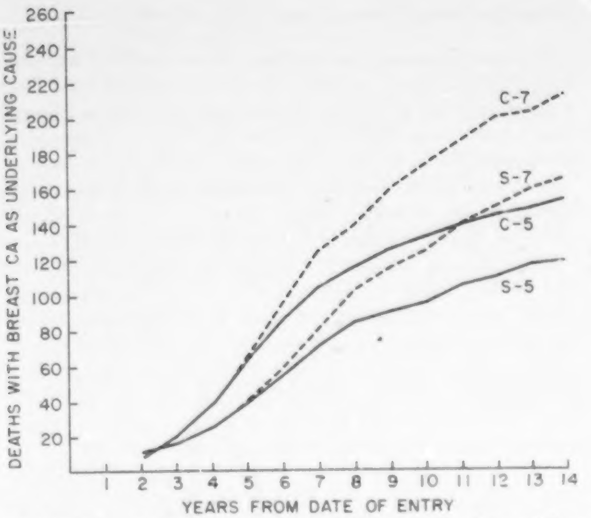
The primary measure in the determination of the efficacy of screening is the differential between study women (those screened one time or more plus those who refuse screening) and control women in the number or rate of deaths with breast cancer as the underlying cause. Included are *a*) deaths due to breast cancer among women with histologically confirmed breast cancer and *b*) deaths among women with breast cancer as the underlying cause of death but with no histologic confirmation prior to death. Category *b*) consists of deaths among women for whom clinical or autopsy evidence indicated that breast cancer was the underlying cause of death. There were 9 and 16 such cases in the study and control groups, respectively, during the first 10 years after entry.

Follow-up periods of 5, 7, 10, and 14 years from date of entry are included to indicate changes in relationships as observations progress from short to intermediate to long intervals of follow-up.

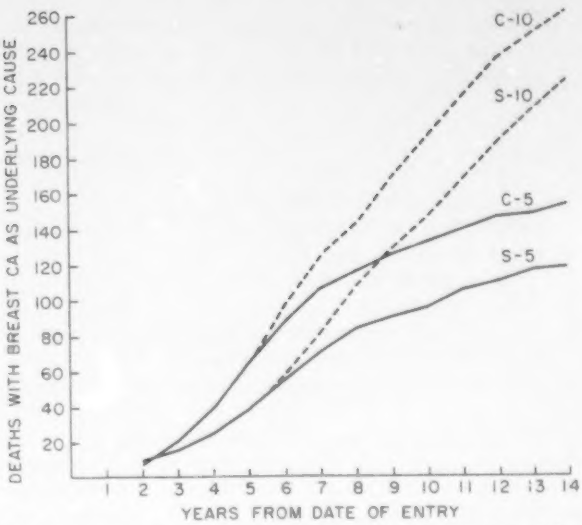
Text-figure 1 displays two trend series. The curves representing cumulative breast cancer mortality from entry date among women with breast cancer diagnosed in the first 5 years have previously served as the basis for conclusions about the impact of periodic screening. Five years has been of interest because it includes an average of 3.5 years of screening and 1.5 years post screening—an interval that extends only moderately beyond the point when women would have been due for an additional examination if the program had continued. The gap between the curves for the

---

[8] In the total study group, there were 176 women alive at the start of follow-up interval 9.5–10 yr; over the next 1.5 yr 12 women had incomplete exposure; at the start of interval 11–11.5 yr, there were 146 women alive, 29 of whom had incomplete exposure by the end of yr 12. Corresponding figures for the control group are similar.



TEXT-FIGURE 1.—Cumulative breast cancer deaths by time interval from date of entry. S-5 and C-5 refer to breast cancer deaths within 5 yr of entry; S-7 and C-7 refer to corresponding situation for cancers diagnosed within 7 yr of entry. S=total study; C=controls.



TEXT-FIGURE 2.—Cumulative breast cancer deaths by time interval from date of entry. S-5 and C-5 refer to breast cancer deaths among cancers diagnosed within 5 yr of entry. S-10 and C-10 refer to corresponding situation for cancers diagnosed within 10 yr of entry. S=total study; C=controls.

study and control groups widens numerically until year 6 or 7 from entry and then remains fairly constant through year 14 (table 2).

Addition of breast cancer deaths to cases diagnosed through year 7 results in increased numerical differentials between study and control groups; no further increases occur with the inclusion of mortality among cases diagnosed in years 8–10 (text-fig. 2). From this, it would appear that mortality due to breast cancer among cases detected starting 3–3.5 years after screening ended became very similar for study and control groups of women.

Thus far, the discussion has been concerned with numerical differences. For purposes of estimating the influence of screening on reduction in the breast cancer mortality rate of a population, relative differences are important. Table 2 shows that the percent decrease becomes smaller with increases in duration from entry. This follows from the constancy in arithmetic differences just presented. Addition of breast cancers diagnosed through year 10 also reduces the differential between study and control groups in breast cancer mortality. The attenuation reflects the effect on breast cancer mortality in a population that participated in screening, because the cases are added long after screening ends. The magnitude of the attenuation is appreciable as suggested by the "observed" percentages in text-figure 3.

TABLE 2.—*Cumulative numbers of deaths due to breast cancer by selected time intervals from date of entry*

Interval to breast cancer diagnosis, yr	No. of breast cancers[a]	No. of deaths with breast cancer as underlying cause through following yr after entry: 5	7	10	14
Within 5					
Study	306	39	71	95	118
Control	300	63	106	133	153
Difference, %		(38.1)[b]	(33.0)[c]	(28.6)[b]	(22.9)[b]
Within 7					
Study	425	39	81	123	165
Control	443	63	124	174	212
Difference, %		(38.1)[b]	(34.7)[c]	(29.3)[c]	(22.2)[b]

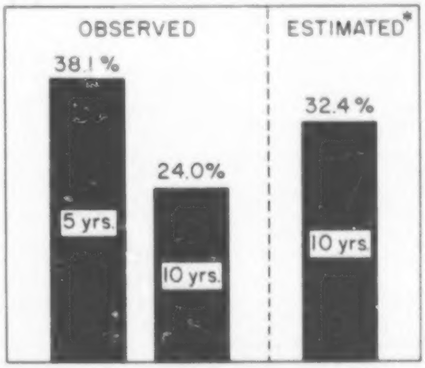
[a] No. indicate breast cancers histologically confirmed within a specified interval after entry plus deaths among women with breast cancer as the underlying cause but with no histologically confirmed diagnosis prior to death.

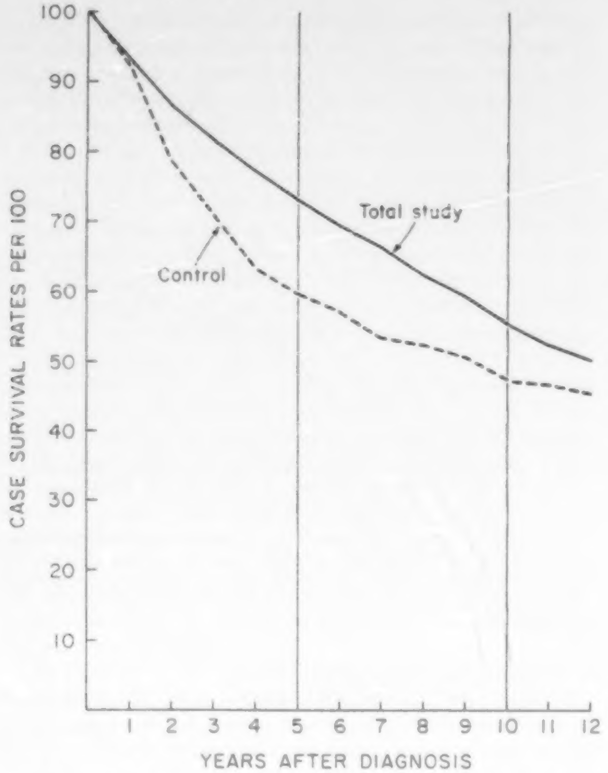
[b] $0.01<P<0.05$. Conditional 2-tailed test of the ratio between 2 Poisson parameters (study:control No. of deaths due to breast cancer) applied.

[c] $P<0.01$. Statistical test same as explained under footnote *b*.



*Estimated under assumption screening program renewed in years 6-10 after entry.

TEXT-FIGURE 3.—Difference between total study and control group deaths due to breast cancer 5 and 10 yr after entry.



TEXT-FIGURE 4.—CSR by interval from diagnosis in total study breast cancer patients and in controls.

Under the assumption that a new cycle of screening in years 6–10 among the women aged 45–64 years resulted in the same reduction in mortality as that found in years 1–5, the margin between study and control groups is 32.4%. This is to be compared with a differential of 24.0% under the condition of no continuation in screening as in the HIP study. Nevertheless, there is some decrease between the 5-year effect of screening and the effect over a 10-year period.

TABLE 3.—*Cumulative CSR (per 100) among confirmed breast cancer cases*[a]

Population	No. of cases	CSR through following yr after diagnosis:[b] 5	10	12
Total study	303	73.9	54.8	50.4 (2.9)
Detected through screening	132	87.1	64.4	59.7 (4.3)
Screened but not detected through screening	93	62.4	46.2	44.7 (5.2)
Refused screening	78	65.4	48.7	41.9 (5.6)
Control	294	59.5	46.3	43.1 (2.9)
Total study, adjusted[c]	303	71.3	53.8	48.9 (2.9)

[a] Included are cases histologically confirmed within 5 yr of entry.

[b] *Numbers in parentheses* are standard errors due to sampling variability.

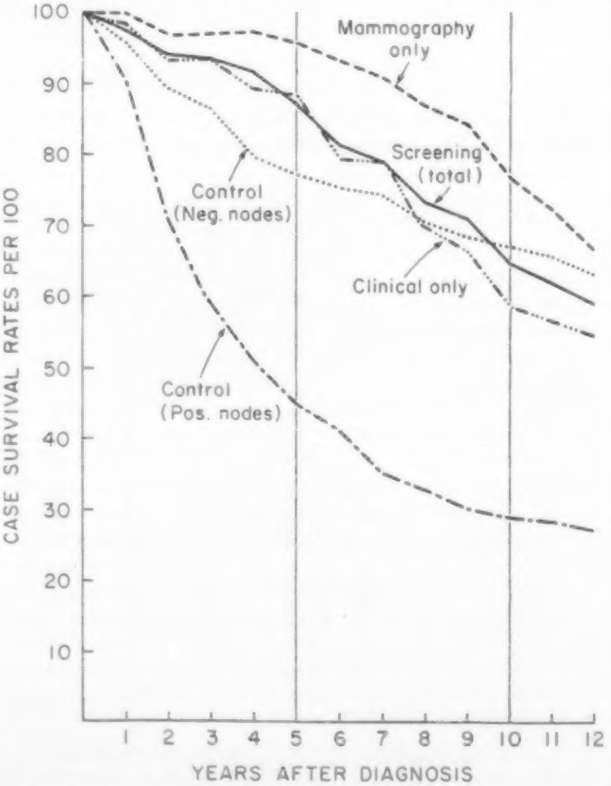
[c] Lead time of 1 yr is included for cases detected through screening. The adjusted CSR through yr *n* is derived as a weighted average of the rates for screened cases (yr $n+1$), screened but not detected through screening (yr *n*), and refused screening (yr *n*).

Case Survival Differentials

Past presentations on mortality from the HIP study parallel the discussions of mortality due to breast cancer with a consideration of CFR, adjusted to take into account an estimated 1-year lead time in the detection of cases through screening (*8*). In general, the results have been highly consistent with those from the analysis of the population-based breast cancer mortality data. A reason for turning to the CFR has been that this is the only possible approach to the examination of the course of mortality related to the screening process itself, i.e., how CFR vary with the mode of detection (mammography or clinical examination) and with the round of screening examinations (initial examination vs. subsequent screenings). There are major restrictions in the interpretation of such CFR because of the uncertainty about how lead time or length-biased sampling, previously discussed, varies with the subgroup of cases detected.

The data to be discussed from this point represent a shift from CFR to CSR. All of the considerations related to CFR are applicable to CSR. The shift to CSR is useful because it places the experience in the study within the context of the usual analysis of breast cancer experience as exemplified by publications from the Cancer Surveillance, Epidemiology, and End Results (SEER) Program (*6*).

Text-figure 4 and table 3 show that screening has had a profound effect on the contour of the trend in cumulative CSR among breast cancer cases diagnosed in the total study



TEXT-FIGURE 5.—CSR by interval from diagnosis of breast cancers detected in screening and control cases.

TABLE 4.—*CSR (per 100) among breast cancer cases detected on screening by modality and control cases*[a]

Breast cancer category of cases	No. of cases	CSR through following yr after diagnosis:[b] 5	10	12
Detected through screening[c]				
Total	132	87.1	64.4	59.7 (4.3)
Mammography only	44	95.5	77.3	67.8 (7.1)
Clinical only	59	88.1	59.3	55.9 (6.5)
Mammography and clinical	29	72.4	55.2	55.2 (9.2)
Control

Positive nodes[d]	123	44.7	29.3	27.4 (4.0)

[a] Included are cases histologically confirmed within 5 yr of entry.

[b] *Numbers in parentheses* are standard errors due to sampling variability.

[c] Initial evidence for biopsy recommendation made independently by the two modalities.

[d] Classification based on histologic evidence of axillary nodal involvement. Not shown are 35 cases with unknown nodal involvement.

group within 5 years after entry. The corresponding control cases have a marked convex curve similar to what is seen in general population series based on relative CSR. In contrast, the total study group barely begins to flatten out at year 10, and, in fact, a linear regression equation fits the time series quite well.

Clearly, within this time period there has been a fundamental alteration in the survival experience among breast cancer cases in the study group. The large bulge between the two trend lines is in the interval 4–8 years post diagnosis. At all subsequent points on the survival curve for the study group, the rate in the control group is 3–4 years earlier, which is well beyond the effect of introducing a 1-year average lead time for cases detected through screening, and provides a basis for estimation of person-years of life gained by the study group. Relative survival rates are currently being developed that take into account age distributions of breast cancer cases detected in the HIP study and age-specific general mortality in the study and control groups. Preliminary results indicate that the relationships discussed in this paper are not materially affected when based on relative survival rates.

Text-figure 5 and table 4 give further evidence of the complex changes that occur in cumulative CSR in a screening program. The solid line represents rates among all cases detected through sceening and is slightly concave. Data plotted for subgroups of these cases are based on small numbers and are subject to large sampling variability. Nevertheless, it would appear that the trend in CSR for cases detected on mammography only is decidedly concave. For "clinical only" cases, the trend is slightly concave. In contrast, the control cases with negative nodes show a modest convex trend in CSR, and by 12 years post diagnosis the cumulative CSR in this group is higher than that in the clinical only cases (≈3/4 of which were diagnosed with negative nodes). Finally, the difference between cumulative CSR for mammography only and clinical only cases appears to peak in year 10 after diagnosis. Some reductions may then occur. Only additional years of observation will determine whether this represents the start of closure or just chance variation. As expected, a wide gap persists between the rates for control cases with positive nodes and all of the other rates.

Mortality by Age

The last issue to be discussed in this paper concerns the much debated question whether the lowered mortality from breast cancer among study women is related to age at entry. Table 5 indicates that the direction of the difference is in favor of the study group at all ages. However, the firmest statements have been related to age group 50–59 years, which showed a statistically significant difference through year 10 ($P<0.05$); in year 14 the difference was not significant ($P>0.10$).

A major issue that has arisen concerns the situation in the age group 40–49 years at entry (*11, 12*) when there has been an increasing differential in breast cancer mortality in favor of the study group. At no time has the difference been statistically significant. In addition, the reason for our conclusion that the study has not demonstrated a benefit at ages under 50 is the observation that for this age group the smaller number of breast cancer deaths in the study group is almost entirely attributable to fewer deaths among cases diagnosed after women advanced to ages 50–54 years.

The rationale for examination of data by age at diagnosis in addition to age at entry is that a repetitive screening program that begins at young ages would eventually show benefits as women advanced beyond age 50, according to the HIP study. The relevant group of women were 45–49 years of age at entry; increasing proportions of these women passed their 50th birthday in successive rounds of screening.

As noted in table 6, the observed difference in numbers of deaths due to breast cancer between study and control groups 45–49 years old at entry (28 vs. 35, respectively, in 14 yr of follow-up) is attributable to the situation among cases diagnosed when the women were 50–54 years of age. The question that might be raised is whether this finding reflects relatively large numbers in the study group of breast cancer cases diagnosed under age 50 and small numbers at 50–54 years of age. However, ratios between deaths and cancer cases classified by age at diagnosis show no difference

TABLE 5.—*Breast cancer deaths by age at entry 5 and 14 years from entry*[a]

Age at entry, yr	No. of deaths through following yr after entry: 5, Study	5, Control	14, Study	14, Control
Total	39	63	118	153
40–49	19	20	46	61
40–44	9	11	18	26
45–49	10	9	28	35

40–44	7	11	17	15
45–49	11	15	32	31
		Age at entry 45–49 yr		
45–54	28	35	68	68
45–49	18	12	40	30
50–54	10	23	28	38

[a] Included are deaths with breast cancer as an underlying cause among breast cancers diagnosed during the first 5 yr after entry.

between study and control groups at ages 45–49 (0.45 vs. 0.40), but they show a major difference at ages 50–54 (0.36 vs. 0.61).

Women 40–44 years old at entry remained under 50 in the interval 5 years after entry. If the deaths are aggregated by age at diagnosis, there is no difference between the study and control groups at 45–49 years (11+18, study group vs. 15+12, control group). The numbers at 40–44 years, age at diagnosis, are too small for meaningful assessment.

DISCUSSION

Follow-up in the HIP randomized trial for determination of efficacy of periodic screening for breast cancer with mammography and palpation of the breast has started to produce information beyond the short to intermediate periods after the start of screening. Results continue to be promising for a role for screening in secondary prevention of breast cancer mortality, although some changes are taking place in the magnitude of differentials that indicate effects.

It seems clear that repetitive screening has led to about a 30% reduction in breast cancer mortality over a 10-year period. The impact of screening on mortality was felt rapidly, and the margin between study and control groups of women in mortality due to breast cancer reached a peak in the first 6–7 years after screening started. The arithmetic gains made by year 7 have been maintained through year 14; relative gains have declined to about 20%. Information from follow-up now under way will determine the nature of changes in differentials over the long run, thereby providing a basis for deriving estimates of person-years of life saved through screening.

Cumulative CSR have been exceptionally favorable among women with breast cancer detected through screening after allowance is made for an estimated 1-year lead time. This accounts for the entire difference between the total study group (screenees and refusers combined) and the control group in their CSR through year 12 after diagnosis of breast cancer. Nevertheless, as the interval from diagnosis increases, trends in CSR differ among various subgroups, the net effect of which is to reduce the differential between the study and control groups' rates. In the early years, cases detected on screening had relatively high CSR even when compared with the rates for control cases diagnosed with negative nodes. But with follow-up approaching 10 years, the advantage is eliminated.

CSR among "mammography only" cases were extraordinarily high the first 5 years after diagnosis and then started to decrease fairly rapidly. One possible explanation is that the mammography only cases were markedly affected by the lead time and length-biased sampling factors. Accordingly, the experience thus far indicates that caution needs to be exercised in drawing conclusions about the advantage for long-term prognosis attributable to screening with mammography from rates over a short period. Differentials in breast cancer mortality by age at entry may also be entering a new phase. From the early years of the study, screening's impact on mortality has appeared at ages 50–59; at entry ages 40–49, study-control differences show up later (although not statistically significant at any time). A complicating factor is the age at diagnosis, which, when introduced in the case of the age group 45–49, strongly suggests that whatever gain may have occurred is attributable to cases diagnosed after the women passed their 50th birthday. At this point, the prudent conclusion is that for ages under 50 years, the HIP study does not provide evidence that screening has had an effect on mortality. Small numbers may be a factor as well as the level of effectiveness of case detection under screening conditions in the 1960's.

All of the preceding observations are derived from an experiment in which mammography was in an earlier stage of development than it is now, and that screening ended after the offering of an initial examination and three additional screening examinations at annual intervals to women in the study group. Despite these limitations, there have been gains in the saving of lives from breast cancer or postponement of death among women with breast cancer. While it is important to assess the longer run impact of screening, the gains have extended over a sufficiently long period of time (12–14 yr) to be significant.
